TABLE OF CONTENTS

TABLE OF CONTENTS 15-i
LIST OF TABLES 15-iv
LIST OF FIGURES 15-ix
PHOTOGRAPHS 15-xiv
LIST OF APPENDICES 15-xiv
ACRONYMS AND ABBREVIATIONS 15-xvi
15. FISH AND AQUATIC INVERTEBRATES 15.1-1
15.1 Fish—Mine Study Area 15.1-1
15.1.1 Introduction 15.1-1
15.1.1.1 Regional Description 15.1-2
15.1.2 Study Objectives 15.1-7
15.1.3 Study Area 15.1-9
15.1.4 Scope of Work 15.1-9
15.1.5 Methods 15.1-9
15.1.5.1 Aquatic Habitat Assessments 15.1-9
15.1.5.2 Fish Assemblage Surveys 15.1-11
15.1.5.3 Instream Flow Habitat Studies 15.1-15
15.1.6 Results and Discussion 15.1-19
15.1.6.1 North Fork Koktuli River 15.1-20
15.1.6.2 South Fork Koktuli Watershed 15.1-42
15.1.6.3 Upper Talarik Watershed 15.1-66
15.1.6.4 Koktuli River Mainstem 15.1-88
15.1.7 Summary 15.1-92
15.1.8 References 15.1-92
15.1.9 Glossary 15.1-100
15.2 Macroinvertebrates and Periphyton—Mine Study Area 15.2-1
15.2.1 Introduction 15.2-1
15.2.2 Study Objectives 15.2-1
15.2.3 Study Area 15.2-1
15.2.4 Scope of Work 15.2-2
15.2.5 Macroinvertebrate Methods 15.2-3
15.2.5.1 Field Sampling Protocol 15.2-3
15.2.5.2 Laboratory Procedures 15.2-5
15.2.5.3 Data Analysis 15.2-6
15.2.6 Periphyton Methods 15.2-7
15.2.6.1 Field Sampling Protocol 15.2-7

15.2.6.2 Laboratory Procedures 15.2-9
15.2.6.3 Data Analysis 15.2-10
15.2.7 Results and Discussion 15.2-11
15.2.7.1 Macroinvertebrates 15.2-11
15.2.7.2 Periphyton 15.2-14
15.2.8 Summary 15.2-15
15.2.9 References 15.2-16
15.2.10 Glossary 15.2-17
15.3 Fish—Transportation Corridor Studies 15.3-1
15.3.1 Introduction 15.3-1
15.3.2 Study Objectives 15.3-2
15.3.3 Study Area 15.3-2
15.3.4 Scope of Work 15.3-3
15.3.5 Methods 15.3-3
15.3.5.1 Aquatic Habitat Assessments 15.3-3
15.3.5.2 Water Quality Measurements 15.3-4
15.3.5.3 Fish Distribution Studies 15.3-4
15.3.6 Results and Discussion 15.3-4
15.3.6.1 Upper Talarik Watershed Group 15.3-4
15.3.6.2 Newhalen Watershed Group 15.3-7
15.3.6.3 Isolated Watershed Group 15.3-9
15.3.6.4 Roadhouse/Northeast Bay/Eagle Bay Watershed Group 15.3-10
15.3.6.5 Youngs/Chekok/Canyon Watershed Group 15.3-13
15.3.6.6 Knutson Bay/Pedro Bay Watershed Group 15.3-15
15.3.6.7 Pile Bay/Lonesome Bay Watershed Group 15.3-17
15.3.6.8 Iliamna River Watershed Group 15.3-18
15.3.7 Summary 15.3-21
15.3.8 References 15.3-22
15.3.9 Glossary 15.3-23
15.4 Macroinvertebrates and Periphyton—Transportation Corridor Study Area 15.4-1
15.4.1 Introduction 15.4-1
15.4.2 Study Objectives 15.4-1
15.4.3 Study Area 15.4-1
15.4.4 Scope of Work 15.4-1
15.4.5 Macroinvertebrate Methods 15.4-2
15.4.6 Periphyton Methods 15.4-2
15.4.7 Results and Discussion 15.4-2
15.4.7.1 Macroinvertebrates 15.4-2
15.4.7.2 Periphyton 15.4-3
15.4.8 Summary 15.4-4
15.4.9 References 15.4-4
15.4.10 Glossary 15.4-4

15.5 Zooplankton—Iliamna Lake 15.5-1
15.5.1 Introduction 15.5-1
15.5.2 Summary of Results and Discussion 15.5-1
15.5.3 References 15.5-2
15.5.4 Glossary 15.5-2

LIST OF TABLES

Table 15.1-1, Fish Resource Studies by Major Study Category Conducted Within the Mine Study Area Watersheds, 2004-2008

Table 15.1-2, Watershed Areas of the North Fork Koktuli River, South Fork Koktuli River, Upper Talarik Creek, and Koktuli River within the Mine Study Area as Compared to Major River Systems in the Bristol Bay Drainage

Table 15.1-3, Designated Stream Reaches in the North Fork Koktuli Watershed

Table 15.1-4, Range of Summer (June, July, and August) Water Temperatures in the North Fork Koktuli Watershed

Table 15.1-5, United States Forest Service Alaska Region Channel Type Legend

Table 15.1-6, Area and Frequency of Off-Channel Waterbodies by Habitat Type in the North Fork Koktuli Watershed

Table 15.1-7, Hydrologic Connectivity of Off-Channel Waterbodies by Habitat Type in the North Fork Koktuli Watershed

Table 15.1-8, Regional Water Quality Data Comparison

Table 15.1-9, Instream Flow Transects by Reach, Habitat Type, and River Kilometer for the North Fork Koktuli Watershed

Table 15.1-10, Number of Physical Habitat Simulation Instream Flow Transects in the Mine Study Area and Transect Weightings by Habitat Type

Table 15.1-11, Range of Flows Offering 90 Percent or More of the Maximum Habitat Area for Various Categories and Life Stages of Fish in Three North Fork Koktuli River Reaches

Table 15.1-12, Fish Species Found in the North Fork Koktuli Watershed, 2004-2008

Table 15.1-13, Fish Catch per Unit Effort by Channel Type in North Fork Koktuli River Reach NFK-C

Table 15.1-14, Anadromous Salmonid Fishes Found by Reach in the North Fork Koktuli Watershed, 2004-2008

Table 15.1-15, Adult Salmon Statistics for the Nushagak District, Nushagak River, and the North and South Fork Koktuli Watersheds

Table 15.1-16, Spawning Salmon Observations in North Fork Koktuli River Reaches during 2008 Aerial Surveys

Table 15.1-17, Non-anadromous Salmonid Fishes Found by Reach in the North Fork Koktuli Watershed, 2004-2008

Table 15.1-18, Subsistence Use of Non-anadromous Salmonid Fishes in Iliamna, Newhalen, and Nondalton

Table 15.1-19, Non-salmonid Fishes Found by Reach in the North Fork Koktuli Watershed, 2004-2008

Table 15.1-20, Designated Stream Reaches in the South Fork Koktuli Watershed

Table 15.1-21, Range of Summer (June, July, and August) Water Temperatures in the South Fork Koktuli Watershed

Table 15.1-22, Area and Frequency of Off-channel Waterbodies by Habitat Type in the South Fork Koktuli Watershed

Table 15.1-23, Hydrologic connectivity of Off-channel Waterbodies by Habitat Type in the South Fork Koktuli Watershed

Table 15.1-24, Instream Flow Transects by Reach, Habitat Type, and River Kilometer for the South Fork Koktuli Watershed

Table 15.1-25, Range of Flows Offering 90 Percent or More of the Maximum Habitat Area for Various Categories and Life Stages of Fish in Three South Fork Koktuli River Reaches

Table 15.1-26, Fish Species Found in the South Fork Koktuli Watershed, 2004-2008

Table 15.1-27, Fish Catch per Unit Effort by Channel Type in the South Fork Koktuli Watershed

Table 15.1-28, Anadromous Salmonid Fishes Found by Reach in the South Fork Koktuli Watershed, 2004-2008

Table 15.1-29, Spawning Salmon Observations in South Fork Koktuli River Reaches during 2008 Aerial Surveys

Table 15.1-30, Non-anadromous Salmonid Fishes Found by Reach in the South Fork Koktuli Watershed, 2004-2008

Table 15.1-31, Non-salmonid Fishes Found by Reach in the South Fork Koktuli Watershed, 2004-2008

Table 15.1-32, Designated Stream Reaches in the Upper Talarik Watershed

Table 15.1-33, Range of Summer (June, July, and August) Water Temperatures in the Upper Talarik Watershed

Table 15.1-34, Area and Frequency of Off-channel Waterbodies by Habitat Type in the Upper Talarik Watershed

Table 15.1-35, Hydrologic Connectivity of Off-channel Waterbodies by Habitat Type in the Upper Talarik Watershed

Table 15.1-36, Instream Flow Transects by Reach, Habitat Type, and River Kilometer for the Upper Talarik Watershed

Table 15.1-37, Range of Flows Offering 90 Percent or More of the Maximum Habitat Area for Various Categories and Life Stages of Fish in Five Upper Talarik Creek Reaches

Table 15.1-38, Fish Species Found in the Upper Talarik Watershed, 2004-2008

Table 15.1-39, Fish Catch per Unit Effort by Channel Type in the Upper Talarik Watershed

Table 15.1-40, Anadromous Salmonid Fishes Found by Reach in the Upper Talarik Watershed, 2004-2008

Table 15.1-41, Adult Salmon Statistics for the Naknek-Kvichak District, Kvichak River, and Upper Talarik Watershed

Table 15.1-42, Spawning Salmon Observations in Upper Talarik Creek Reaches during 2008 Aerial Surveys

Table 15.1-43, Non-anadromous Salmonid Fishes Found by Reach in the Upper Talarik Watershed, 2004-2008

Table 15.1-44, Non-salmonid Fishes Found by Reach in the Upper Talarik Watershed, 2004-2008

Table 15.1-45, Fish Species Found in the Upper Koktuli River Mainstem, 2004-2008

Table 15.1-46, Juvenile and Adult Fishes Found in the Upper Koktuli River Mainstem, 2004-2008

Table 15.2-1, Macroinvertebrate and Periphyton Sampling Sites and Methods, Mine Study Area, 2004 through 2007

Table 15.2-2, Macroinvertebrate Taxa Identified in Samples Collected in the Bristol Bay Drainages

Table 15.2-3, Chironomidae Taxa Identified in Samples Collected in the Bristol Bay Drainages

Table 15.2-4, Macroinvertebrate Metrics for Data Collected Using the ASCI Method, Mine Study Area, June and August 2004

Table 15.2-5, Macroinvertebrate Metrics for Data Collected Using the Drift-net Method, Mine Study Area, June and August 2004

Table 15.2-6, Macroinvertebrate Metrics for Data Collected Using the ASCI Method, Mine Study Area, June 2005

Table 15.2-7**,** Macroinvertebrate Metrics for Data Collected Using the Surber Method, Mine Study Area, June 2005

Table 15.2-8, Macroinvertebrate Metrics for Data Collected Using the ASCI Method, Mine Study Area, June 2007

Table 15.2-9**,** Macroinvertebrate Metrics for Data Collected Using the Surber Method, Mine Study Area, June 2007

Table 15.2-10, *P*-values of Response Variables for Repeated-measures ANOVA of Surber Samples, 2005 and 2007

Table 15.2-11, *P*-values of Response Variables for Paired T-test of ASCI Samples, Upstream versus Downstream Sites on Upper Talarik Creek and the North Fork Koktuli, 2005 and 2007

Table 15.2-12, *P*-values of Response Variables for Repeated-measures ANOVA of Surber Samples, Upstream versus Downstream Sites on Upper Talarik Creek and the North Fork Koktuli, 2005 and 2007

Table 15.2-13, Ambient Water-quality Measurements, Mine Study Area, June 2004

Table 15.2-14, Ambient Water-quality Measurements, Mine Study Area, August 2004

Table 15.2-15**,** Ambient Water-quality Measurements, Mine Study Area, June 2005

Table 15.2-16**,** Ambient Water-quality Measurements, Mine Study Area, June 2007

Table 15.2-17, *P*-values of Response Variables for Repeated-measures ANOVA of Surber Samples for the Relationship between Water-quality and Macroinvertebrate Metrics for Sites on Upper Talarik Creek, North Fork Koktuli, and South Fork Koktuli, 2005 and 2007

Table 15.2-18, *P*-values of Response Variables for Simple Linear Regression of ASCI Samples for the Relationship between Water-quality and Macroinvertebrate Metrics for Sites on Upper Talarik Creek, North Fork Koktuli, and South Fork Koktuli, 2004, 2005, and 2007

Table 15.2-19, Average Scores for Habitat-quality Parameters, Mine Study Area, 2004 and 2005

Table 15.2-20, Periphyton Diatom Taxa Identified in Samples Collected in the Bristol Bay Drainages, August 2004

Table 15.2-21, Periphyton Metrics for Data Collected Using the Modified EPA RBP Method in June and August 2004 and Chlorophyll-*a* Sampling in June 2005 and 2007, Mine Study Area

Table 15.3-1, Watershed Affiliation of Survey Sites along the Representative Road Alignment in the Transportation Corridor, Bristol Bay Drainages Study Area

15. FISH AND AQUATIC INVERTEBRATES

15.1 Fish—Mine Study Area

15.1.1 Introduction

Numerous fish resource studies were conducted in the mine study area (Figure 15.1-1) from 2004 through 2008. These studies were conducted along a length of more than 236 miles (380 kilometers) of stream habitat in the North Fork Koktuli (NFK), South Fork Koktuli (SFK), and Upper Talarik (UT) watersheds, as well as in the upper Koktuli River (KR). Chapter 15, Section 15.1 of the Environmental Baseline Document (EBD) is a summary of the methods and results of the fish resource studies conducted in the mine study area during the 2004 through 2008 study period. In addition, Chapter 15, Section 15.1 synthesizes results of these studies with data collected during other Pebble Project studies in other resource areas, such as water quality, aquatic macroinvertebrates, hydrology, and wildlife.

Due to the large volume of fish resource data collected, there are seven appendices to Chapter 15, Section 15.1. These appendices are listed below.

- Appendix 15.1A, Fish Species Life History Information
- Appendix 15.1B, Reach Analysis
- Appendix 15.1C, Instream Flow: Main Channel Habitat Study
- Appendix 15.1D, Off-channel Habitat
- Appendix 15.1E, Open River Water Temperature Model
- Appendix 15.1F, Fluvial Geomorphology Studies
- Appendix 15.1G, Naming Convention Used for Waterbodies in the Mine Study Area

Appendices 15.1A and 15.1G are intended to provide readers with supplemental information that will enhance the reading of this EBD section. Appendix 15.1A describes the current distribution, behavioral and reproductive life history, and habitat requirements of fish species that may potentially be present in the mine study area based on previously documented species distributions in the Bristol Bay Basin. Appendix 15.1G describes the naming convention used to specify the numerous tributary streams and lakes in the study area. The other five appendices (i.e., Appendices 15.1B, 15.1C, 15.1D, 15.1E, and 15.1F) provide detailed methods and results of the EBD fish resource studies in a technical format.

In order to present the data in an ecologically meaningful framework, results of the fish resource studies are presented specific to each of the four watersheds included in the mine study area: the NFK, SFK, UT, and KR. In addition, the results discussion uses a reach-analysis approach to assess spatial trends throughout each of the major watersheds. Specifically, 18 distinct hydrological reaches within the NFK, SFK, and UT watersheds were delineated by R2 Resource Consultants, Inc. (R2), and Buell & Associates, Inc. based on a review of maps and existing data associated with multidisciplinary parameters influencing channel function. Parameters considered included: channel and valley morphology, geology, stream discharge, and surface water temperature. The review resulted in the delineation of six, five, and seven mainstem EBD reaches within the NFK, SFK, and UT, respectively (Figure 15.1-2). Additionally, tributaries and off-channel habitats within the three basins were assigned to one of the 18 mainstem

reaches based on the location of the tributary-mainstem confluence. Each tributary drainage was assigned to the mainstem reach that it flowed into, while off-channel habitats were assigned based on their proximity to the mainstem channel. While no formal reach delineation occurred for the mainstem KR, the portion of the KR in which fish resource studies were conducted during the 2004 through 2008 study period has been treated in the same manner as the other 18 delineated reaches for purposes of results analysis and presentation (Figure 15.1-2). The reach-analysis approach used herein is consistent with that used in Appendix 15.1B, which presents detailed results specific to each of the 19 delineated reaches for several of the fish resource studies.

To further facilitate the presentation of data, numerous graphics (including tables, figures, and maps) are included in Section 15.1. It is important for readers to note that these graphics were selected as representative examples of the larger body of data (as presented in the detailed technical Appendices 15.1B through 15.1F and in other EBD chapters) as a way to provide readers with summary images of fish resource patterns in the mine study area. Readers interested in more detailed results than those presented here should refer to the technical appendices and/or other EBD chapters for detailed information. When data sources for the selected graphics fall outside the realm of Section 15.1 and/or its associated appendices, references to the data source are provided in notes accompanying the tables and figures. In addition, the following map production notes will enhance the viewing of the maps included herein.

1. All maps are electronic and, although they can be printed for convenience, some detail is visible only when zoomed in to a finer scale on the electronic form. For example, some bar graphs included on the maps have data points that are close to zero, such that they appear to be absent on printed versions. However, when viewed electronically, readers will be able to more readily view such data points.

2. The maps were created and produced in a series, thus the legend was built for the map series and, as such, contains all possible data types for that series. Furthermore, the legend for any individual watershed map within a series may contain symbols for data that were not documented within that watershed and thus are not depicted on the map itself.

3. The map background orthophoto was generated by aerial photogrammetric methods using aerial photographs dated July 2004. As a result, the stream network seen on the image is represented as it was at one point in time during July 2004. In addition, locations were recorded using handheld Global Positioning System (GPS) units and thus have some level of error associated with them. This error is generally less for waypoints taken on the ground (on the order of a meter or two) than those taken from the air (up to 400 m). As a result of these two factors, GPS measurement error and a fixed orthophoto photo date, there are some data points on the maps that do not appear to be contained within a stream channel but are located nearby. When these data were checked for QAQC and found to be correct, then the marker identifying that point was left where it fell on the map and was not moved to be contained within a stream channel or waterbody. This is particularly important to keep in mind when viewing data collected in off-channel areas.

15.1.1.1 Regional Description

The following subsections contain brief descriptions of watershed characteristics and processes influencing the nature and condition of fish habitat and other aquatic resources in the mine study area. The fish resources of the study area are also described. Additionally, other wildlife species present in the

mine study area that are known to prey on fish are discussed herein, given potential predation effects that these species may have on fish distribution and abundance. Details on specific watershed physical characteristics in the study area, including climate, geology, physiography (topography and landforms), soils, surface water hydrology, and vegetation are provided in Chapters 2, 3, 4, 5, 7, and 13, respectively, and wildlife resources are discussed in detail in Chapter 16.

Climate

In the main part of the Bristol Bay drainages that is comprised of the Nushagak River and Kvichak River watersheds, the climate is transitional between maritime and continental. The narrow strip of Bristol Bay watershed along the northwestern side of the Alaska Peninsula is more maritime. Regional precipitation is greatest from late summer through early winter and is primarily generated by maritime storm systems. The most common circulation pattern consists of atmospheric lows moving in from the North Pacific Ocean along the Aleutian Island chain into the central and eastern Bering Sea (Albanese, 2008). These storms produce a strong southeasterly air flow near ground surface as winds spiral in a counter-clockwise direction toward the center of the low pressure cell. The storms are loaded with maritime moisture, with the heaviest precipitation occurring along the southeastern flanks of the Alaska and Aleutian ranges, outside of the Bristol Bay drainages. Considerable precipitation also occurs within the watershed, especially on higher terrain with southerly to easterly exposure. Less frequently, atmospheric lows situated at Kodiak Island and the Shelikof Strait area result in northeasterly air flows. Moisture is much lower with this flow pattern, but it still may produce precipitation in the main part of the watershed. By mid-winter, the lows tend to move into the central to eastern Gulf of Alaska, resulting in northerly to northwesterly surface-level air flows of colder, drier, continental air. (See Chapter 2 for details on climate.)

The long-term mean annual precipitation at the Iliamna Airport is 26.4 inches (67.1 centimeters), approximately 30 percent of which falls as snow. The average annual precipitation at the Iliamna Airport during the four complete water years of the study period (October 2004 through September 2008) was close to average: 25.3 inches (64.3 centimeters). The mean annual runoff at the USGS gaging stations on the lower reaches of the three mainstem channels in the mine study area (NFK, SFK, and UT) during the study period was 35 to 38 inches (88.9 to 96.5 centimeters), indicating that precipitation in the mine study area is considerably greater than at Iliamna.

Temperature, precipitation, and wind speed in the study area have been assessed at six meteorological stations (Chapter 2). Precipitation at those stations has been highest in the late summer and early fall (August through October) as a result of heavy rains. A secondary peak in precipitation occurs from January through March, when snow forms a persistent winter snow pack. Cold temperatures during the winter were persistent enough that streams generally froze. However, in some reaches of all three stream systems the influence of groundwater inflow has been sufficient to keep segments of the stream ice-free.

Physiography

Physiography, pertaining to the landforms and topographic features of the study area, has been described in Chapter 4 and summarized below. The mine study area encompasses portions of two physiographic divisions: the Nushagak-Big River Hills division and the Nushagak-Bristol Bay Lowlands division (Detterman and Reed, 1973).

The Nushagak-Big River Hills division includes an area of low, rolling hills separated by wide, shallow valleys. The elevation above sea level ranges from approximately 775 feet (236 meters) near the southwestern end of the study area to approximately 3,075 feet (937 meters) on Groundhog Mountain (northeast of Frying Pan Lake) and 2,760 feet (841 meters) on Kaskanak Mountain (west of Frying Pan Lake). The headwaters of the three main watersheds (NFK, SFK, and UT) lie within this division. All three drainage channels are highly sinuous with wide, shallow valleys and oxbow lakes. The NFK originates in the northern portion of the mine study area and flows to the west-southwest for 36 miles (58 km), before joining the SFK near the western extent of the mine study area. The SFK forms west of the Pebble Deposit and then flows south into Frying Pan Lake. From the Frying Pan Lake outlet, the SFK flows west-southwest for 34 miles (55 km), where it joins with the NFK to form the KR in the southwestern portion of the mine study area. The NFK and SFK surround a series of rolling hills west of Frying Pan Lake. The UT flows from its headwaters within the northeast portion of the mine study area to the south-southeast for 39 miles (62 km) into Iliamna Lake. A comparison of longitudinal profiles of the three rivers is depicted on Figure 15.1-4.

The Nushagak-Bristol Bay Lowlands division within the mine study area contains lowlands with abundant swamps and lakes. The topography in this division is relatively flat (maximum relief of a few hundred feet; Chapter 4), with most of the terrain gradually sloping toward Iliamna Lake. This division encompasses the lower portion of UT and a small portion of the lower section of SFK.

Vegetation

The vegetation in the three watersheds within the study area is predominately characterized by Shrub Vegetation Types (Chapter 13). Among these types, Dwarf Shrub Types are most common, accounting for over half the mapped area. Willows and alders cover hillsides, and willows occupy much of the riparian habitats. Forest Vegetation Types are scarcely represented in the study area. Small pockets of balsam poplar stands are found along the rivers. White spruce and paper birch are found in the northeast corner of the mapped area along the Upper Talarik, and form larger stands to the east of the study area in the Newhalen drainage. Wetland communities are common in the study area and have been mapped and described in detail in Chapter 14.

Geology

Glacial deposits formed by regional glaciation during the late-Wisconsin period dominate the surficial geology of the watersheds in the mine study area. Surficial deposits were first mapped by Detterman and Reed (1973) and were more recently studied by Hamilton and Klieforth (2010). The studies indicate that lobes of several large regional glaciers overrode the study area approximately 10,000 to 26,000 years ago, entering the watersheds from the north, northeast and south. Glaciers blocked the three major drainages of the mine study area (NFK, SFK, and UT) at various times. The lowlands at the headwaters of each of the drainages were filled with ice-dammed lakes resulting from glacial blockages. The lake basins are bounded by end moraine deposits and contain hummocky drift deposits with numerous kettle ponds. Terminal moraines enclose younger sets of glacial lakes during subsequent retreat (Hamilton and Klieforth, 2010). Surficial glacial lake deposits are particularly prevalent in the Wiggly Lake basin (upper NFK basin), Frying Pan Lake basin (upper SFK basin), and throughout the middle and upper part of the UT basins (Hamilton and Klieforth, 2010). Glacial lake deposits are generally composed of silt-rich sediment and have poor surface drainage. In contrast, outwash deposits that occur in portions of the NFK and SFK watersheds downstream of the lake basins consist of very porous coarse sediments.

Precipitation, snowmelt, and surface waters infiltrate rapidly in these areas and streams flowing across these deposits lose surface flow and in some reaches can go dry on a seasonal basis. Moraine and glacial drift deposits are also relatively porous and may contain numerous surface kettle ponds that drain to groundwater. The high storage capacity of the thick surficial materials, and to a lesser extent the surface ponds, in the study area attenuates high flows during wet periods and helps maintain base flows during dry periods.

Bedload transport has occurred through several modes and from various sources. Streambed cobble and gravel stones appear to be more angular upstream and more rounded downstream and are thought to have been transported during fall and spring freshets. Bedload also has been transported downstream by ice during breakup. Bedload sources have included the streambed, banks, and eroding terraces. Streambed fine sediment levels were conducive to good survival of incubating salmonid embryos in all three study rivers and appeared to be lowest in the NFK channel.

Fish Resources

The fish resources within the study area include five species of anadromous Pacific salmon, at least four species of non-anadromous salmonids, and numerous non-salmonid fishes. Detailed information regarding each of these species is provided in the specific watershed descriptions that follow. The runs of Pacific salmon inhabiting the study area fall within the Bristol Bay management area, which provides the largest commercial sockeye salmon fishery in the world as well as economically valuable fisheries for Chinook, chum, coho, and pink salmon (Jones et al., 2009). The Bristol Bay management area includes nine major river systems and is divided into five management districts. As a tributary to the Mulchatna and Nushugak rivers, the Koktuli River is a component of the Nushagak Management District. UT, as a tributary to Iliamna Lake and the Kvichak River, is a component of the Naknek-Kvichak Management District.

Non-salmon fishes also represent important components of subsistence and recreational fisheries in the Bristol Bay area. For example, species present in the mine study area that are used for subsistence purposes in the Kvichak River and Iliamna Lake area include arctic grayling, Dolly Varden, rainbow trout, several species of whitefish, burbot, and northern pike (Krieg et al., 2005). Several of these species are also targeted for sport harvest in the Bristol Bay sport fish management area, including arctic grayling, Dolly Varden, rainbow trout, and northern pike (Dye et al., 2006).

Wildlife Resources

Throughout the mine study area, several mammal and bird species that prey on fish have been documented. Many of these species are primarily carnivorous and heavily reliant on fish as part of their diet, while other species exhibit more opportunistic or omnivorous feeding behavior. Fish represent a smaller portion of the diet of the opportunistic feeders. Observations of the various fish predators in the mine study area were made during mammal and bird surveys conducted during the baseline study period. Summaries of the main fish predators are provided below (see Chapter 16 for detailed information).

Brown bears (*Ursus arctos*) are known to seasonally congregate along salmon-bearing streams and feed heavily on salmon during adult salmon migration and spawning seasons. Brown bear presence in the mine study area is well known, and bear observations by various Pebble Project field crews were common throughout the baseline study period. The presence and distribution of brown bears in the study area was

documented during large mammal and other wildlife surveys (Chapter 16, Section 16.2) and in the broader Bristol Bay region during studies by the Alaska Department of Fish and Game (ADF&G; Becker, 2003; Butler, 2007). Black bears (*U. americanus*) also feed on salmon, but are rare in the mine study area and generally avoid salmon-bearing streams when brown bears are present.

Red foxes (*Vulpes vulpes*) and gray wolves (*Canis lupus*) are canine species that consume fish as part of their diet. The red fox is an opportunistic predator and consumes a wide-variety of prey items, including both invertebrates and vertebrates. While gray wolves commonly hunt large mammal species such as caribou (*Rangifer tarandus*), recent studies in coastal Alaska and British Columbia suggest adult salmon may also be an important part of a wolf's diet, particularly during salmon spawning runs (Szepanski et al., 1999; Darimont and Reimchen, 2002; Darimont et al., 2008). Red foxes and gray wolves were observed during wildlife surveys conducted in the mine study area during the baseline study period (Chapter 16, Section 16.2). Pebble Project personnel also commonly reported red fox sightings in the mine study area. Wolf sightings in the mine study area were recorded, but to a lesser degree (Chapter 16, Section 16.2).

River otter (*Lontra canadensis*) and mink (*Neovison vison*) are small furbearing species that feed on a variety of prey items, including fish. These species are associated with riparian and aquatic habitats. River otters were observed in the mine study area in 2004 and 2005 (Chapter 16, Section 16.2), and river otter predation on spawning rainbow trout and other fish species was observed during fish studies conducted by R2 in 2008. While mink are common throughout the Bristol Bay region, they were not observed in the mine study area during the baseline wildlife surveys (Chapter 16, Section 16.2). The lack of direct observation in the mine study area may result from the low detectability of this small riparian species rather than their absence from the area (Cook and MacDonald, 2004a; Cook and MacDonald, 2004b).

Two raptor species in the mine study area—Osprey (*Pandion haliaetus*) and Bald Eagle (*Haliaeetus leucocephalus*)—consume fish as part of their diet. In particular, adult salmon, when available, make up a large part of the diet of Ospreys and Bald Eagles. The presence of these bird species in the mine study area was documented during raptor surveys conducted in 2004 and 2005 (Chapter 16, Section 16.3). Osprey and Bald Eagle nests were generally concentrated around riverine and lacustrine waterbodies.

There are several piscivorous (fish eating) bird species that occur in the mine study area (see Chapter 16, Sections 16.4 and 16.5). Observed species that regularly consume fish as part of their diets include: mergansers (*Mergus* spp.), loons (*Gavia* spp.), Red-necked Grebes (*Podiceps grisegena*), Double-crested Cormorants (*Phalacrocorax auritus*), gulls (*Larus* spp.), and Arctic Terns (*Stema paradisaea*). Yellowlegs (*Tringa* spp.) are also known to occasionally consume fish. Collectively, these species occur throughout the mine study area and are most commonly associated with riverine and lacustrine waterbody habitats.

While beavers (*Castor canadensis*) do not prey on fish, they are known to exert profound effects on hydrology, channel morphology, and aquatic habitat productivity, and subsequently affect the distribution of fish and other aquatic organisms (Butler, 1995; Collen and Gibson, 2001; Rosell et al., 2005). Beavers influence fish distribution and abundance in different ways: beaver activity can result in the creation and maintenance of fish spawning and rearing habitats, and/or beaver dams have the potential to prevent or delay fish movements. Beaver ponds (also referred to as beaver complexes) were common throughout the mine study area and were described as a distinct off-channel habitat type during aquatic habitat surveys conducted from 2004 through 2008. One hundred thirteen active beaver colonies were documented in the mine study area (Chapter 16, Section 16.2).

15.1.2 Study Objectives

The overall goal of the fish resource studies was to describe the baseline fish population characteristics and the aquatic habitat conditions and watershed processes that may potentially influence fish presence, distribution, and relative abundance. Baseline conditions refer to the habitats and associated fish populations and assemblages of aquatic biota as they currently exist in the watersheds. To address this overall goal, 13 studies, broadly consisting of three aquatic habitat assessments, six fish studies, and four instream flow habitat studies, were conducted during the 2004 through 2008 study period (Table 15.1-1). These studies are closely interrelated, yet each individual study was defined by its own specific study objectives.

In several cases, study objectives were geared towards specific types of waterbodies (rivers, streams, tributaries, off-channel habitats, lakes, and ponds) found within the three active river valleys in the mine study area. In particular, the fish resource studies often distinguish between mainstem, tributary, and off-channel habitats. Mainstem habitats are those that are located within the mainstem channel of the focal river or stream. For example, in the NFK watershed, the mainstem channel is the NFK river channel (NFK 1.0). Tributaries are streams that flow into and contribute water to other larger streams. In the example provided above, any of the streams that flow into the mainstem NFK river, such as NFK 1.190 and NFK 1.240, are thus classified as tributaries. Off-channel habitats are considered to be "off-channel", because they are located outside of the mainstem or tributary channel, yet are within the river's active valley. Off-channel habitats may have surface water connections to mainstem and tributary channels when flow levels are high enough to create hydrologic connections. These different types of habitats are depicted in Figure 15.1-4.

The aquatic habitat assessments were designed to provide a detail description of the types and amounts of aquatic habitat available in the mine study area. Specific study objectives for the aquatic habitat assessments are listed below.

- To describe channel morphology and valley form characteristics in mainstem and tributary channels
- To characterize riverine habitat types (e.g., pools, riffles, and runs/glides), their distribution throughout the river, as well as the amount of river and stream habitat available for fish
- To document the locations of special habitat features (e.g., tributaries, springs, seeps, and possible barriers to upstream fish migration) that may influence fish distribution and abundance throughout the mine study area
- To characterize the quality and quantity of off-channel habitat within representative off-channel habitat study areas

Overall, the fish studies were designed to describe fish species assemblages and patterns of fish distribution and abundance in the mine study area, as well as fish use of specific habitat types. The objectives of the fish studies are listed below.

- To document and describe patterns of fish distribution and relative abundance in mainstem, tributary, and off-channel habitats

- To describe and compare fish densities among mainstem, tributary, and off-channel habitat types
- To document fish presence during winter months when ice conditions are present
- To document the spatial and temporal distribution of adult anadromous salmon returning to and spawning in the mine study area
- To obtain annual abundance estimates of adult anadromous salmon

Existing habitats and fish populations are influenced by combinations of local and regional hydrology, geology, and climate. Understanding the current relationships between habitat and flow within the mainstem channels, as well as in off-channel areas, and the hydrodynamic influences on channel form and function are important for characterizing environmental baseline conditions. In addition, fluvial geomorphology studies can be used to describe channel form and to identify the fundamental physical and biological conditions and processes influencing channel morphology and the ways channels may change over time. These fundamental fluvial geomorphic conditions and processes include: the underlying local and upstream geology, hydrology, hydraulics, sediment supply, sediment transport, and biophysical influences. In turn, these various characteristics of channel form and function influence the quantity and quality of aquatic and terrestrial habitat for plants and animals dependent on the river environment for all or part of their life history. Thus, four main types of instream flow habitat studies were conducted in the mine study area during the 2004 through 2008 study period: mainstem channel instream flow habitat studies, off-channel instream flow habitat studies, water temperature monitoring and modeling, and fluvial geomorphology and spawning gravel quality studies. The objectives of these studies are listed below.

- To describe the relationships between stream flow and suitable fish habitat for target species at various life stages.
- To quantify the amount of fish habitat present under baseline flow conditions for target species at various life stages.
- To assess the hydrologic relationships between mainstem channel flow conditions and off-channel habitats
- To describe seasonal and longitudinal surface water temperature regimes in mainstem channels
- To develop flow-sensitive surface water temperature models for mainstem channels
- To characterize fluvial geomorphic conditions in the study area and to link potential changes in hydrology and drainage area through an evaluation of flow and channel forming processes in mainstem channels
- To assess spawning gravel quality and characteristics as influenced by flow and salmon-induced physical disturbance

Collectively, the aquatic habitat assessments, fish assemblage surveys, and instream flow habitat studies are geared towards providing a comprehensive and detailed description of the baseline conditions of fish resources in the mine study area. To further enhance this overview, results of these studies were closely

linked with results from other resource investigations in the mine study area, such as those focused on surface water hydrology (Chapter 7, Section 7.2), surface water quality (Chapter 9, Section 9.1), and aquatic invertebrates (Section 15.2).

15.1.3 Study Area

The fish resource-mine study area for the Pebble Project encompasses three watersheds: the NFK, the SFK, and the UT, as well as a 29-mile (46-km) long portion of the upper KR mainstem in the area immediately downstream of the confluence of the NFK and SFK (Figure 15.1-1). The KR flows for approximately 39 miles (62 km) before entering the Mulchatna River, which flows 44 miles (70 km) to the Nushagak River (Figure 15.1-5). The Nushagak River flows a distance of about 109 miles (175 km) before discharging into Bristol Bay. The UT drains to Iliamna Lake and from there to Bristol Bay via the Kvichak River, a distance of about 56 miles (90 km). The total distance from the Pebble Deposit to Bristol Bay along the three major river pathways is 228, 232, and 150 miles (*including the 33 miles to transit Iliamna Lake*) for the NFK, SFK and UT drainages, respectively. The watershed areas of the NFK, SFK, UT, and KR within the mine study area as compared to their major river basins and the entire Bristol Bay drainage area are provided in Table 15.1-2.

15.1.4 Scope of Work

Fish resource surveys within the mine study area were initiated in 2004 by Northern Dynasty Mines, Inc. (NDM) and were continued by the Pebble Partnership through 2008. The fish resource studies were designed to define and evaluate the physical, chemical, and biological baseline conditions of aquatic habitats and fish assemblages within the mine study area watersheds (Figure 15.1-1). The studies were closely linked with other resource investigations, in particular, those focused on surface water hydrology (Chapter 7, Section 7.2), surface water quality (Chapter 9, Section 9.1), and aquatic invertebrates (Section 15.2). Collectively, the fish resource studies, conducted over the 5-year period (2004 through 2008), can be grouped into three main categories: 1) aquatic habitat assessments, 2) fish assemblage surveys, and 3) instream flow habitat studies. Over the 5 years of study presented in this Chapter, 13 studies have been completed, broadly consisting of three aquatic habitat assessments, six fish studies, and four instream flow habitat studies. The timeframe for these studies, by year and watershed, is presented in Table 15.1-1. Field studies were carried out by HDR Alaska, Inc. (HDR) from 2004 through 2007 and by R2 Resource Consultants, Inc. (R2) in 2008.

15.1.5 Methods

Methods used to conduct the fish resource studies described in Table 15.1-1 are provided in the sections that follow. Due to the large number of studies that were conducted and the ensuing amount of detail related to specific methodologies and protocols, more detailed descriptions of the fish resource survey methods are provided in Appendix E of the EBD, as well in Appendices 15.1C through 15.1F.

15.1.5.1 Aquatic Habitat Assessments

Aquatic habitat surveys in the mine study area were conducted in 2004 through 2008, with each year's effort focused on specific geographic areas, habitat components, or various data gaps (Table 15.1-1). Aquatic habitat surveys were conducted in mainstem, tributary, and off-channel habitats. In addition,

mesohabitat mapping was completed for the mainstem portions of the NFK, SFK, and UT. Data collection methods used for each of these study components are described in the sections that follow.

Mainstem and Tributary Habitat Surveys

The majority of the mainstem channel and tributary habitat surveys used modified Tier 1 and Tier 3 aquatic habitat survey protocols adapted from the United States Forest Service (USFS) *Aquatic Habitat Management Handbook* (USFS, 2001). This methodology allows for habitat data collection at multiple tiers (i.e., Tiers 1, 2, and 3), with Tier 1 representing the broadest level of classification (e.g., reach-scale), and Tiers 2 and 3 finer levels of classification (e.g., meso- and microhabitat units). Such data are collected by conducting foot surveys, or boat surveys in larger rivers, and recording measurements and/or visual estimates of specified habitat parameters.

Modified Tier 1 aquatic habitat survey protocols were used to sample mainstem and tributary habitats in the NFK, SFK, and UT watersheds in 2004, 2007, and 2008 (USFS, 2001; Table 15.1-1). These protocols were used to collect information on channel morphology and valley form at a reach scale, with a reach defined as a section of channel with consistent channel morphology and flow volume. Reach-scale data were collected at channel morphology transects located within each reach. Parameters recorded included: USFS channel type (Paustian et al., 1992), discharge, substrate particle size distribution, bankfull width, bankfull depth, bed width, wetted width, and gradient. These data were collected using a combination of tools, such as a flow meter, Kevlar tape, stadia rod, and clinometer (Photo 15.1-1).

Modified Tier 3 aquatic habitat surveys (USFS, 2001) were conducted in 2004, 2005, 2007, and 2008 to identify and delineate individual habitat types (beaver pond complexes, backwaters/sloughs, ponds/lakes, cascades, pools, riffles, runs/glides, and wetlands) present in mainstem and tributary streams in the NFK, SFK, and UT watersheds (Table 15.1-1). Habitat units were delineated using visual estimation, and several parameters describing each habitat unit were recorded. Parameters such as habitat unit length, width, and depth were measured using either Kevlar tape, stadia rod, or a laser range finder in relatively long or wide habitat units. Visual estimation techniques were used to determine substrate composition and fish cover types. In addition to collecting reach-scale and habitat unit data, the locations of special habitat features (e.g., tributaries, springs, seeps, and possible barriers to upstream fish migration) were also recorded in 2008. For tributaries, seeps, and springs, the percent flow contribution to the mainstem was visually estimated, and water temperatures were measured.

In 2004 through 2007, anecdotal habitat data collection also occurred either in addition to or in lieu of the more formal USFS aquatic habitat survey methods. Anecdotal habitat data were collected in the NFK, SFK, and UT watersheds, and in the upper KR mainstem (Table 15.1-1). Parameters recorded included habitat type, sample length, wetted width, substrate composition, and cover types. While data collection methods are similar to those used for the Tier 3 aquatic habitat surveys (i.e., Kevlar tape, visual estimation), these anecdotal surveys differed from the Tier 3 surveys in that these surveys were conducted to collect data specific to selected fish sampling locations, rather than to delineate contiguous habitat units within a sample reach.

Off-channel Habitat Surveys

Off-channel habitat surveys were conducted from 2005 through 2008 in areas along the mainstem NFK, SFK, and UT river channels where high concentrations of off-channel habitats were found. The off-

channel habitats that were surveyed for habitat data represent a subset of the off-channel habitats encountered along transects established in these areas. Off-channel habitat transects were co-located with mainstem channel instream flow transects. Mainstem channel and off-channel transect establishment, as well as the collection of instream flow habitat data along these transects, is described in Section 15.1.5.3.

Off-channel habitat surveys were conducted using anecdotal habitat data collection in the SFK and UT in 2005 through 2007 and modified Tier 3 aquatic habitat survey protocols in the NFK in 2008 (Table 15.1-1). Methodologies and parameters recorded for the off-channel habitat surveys are similar to those used for the mainstem and tributary habitat surveys described above. Habitat units were delineated using visual estimation, and several parameters describing each habitat unit were recorded. Parameters such as sample length, wetted width, and water depth were measured using either Kevlar tape, stadia rod, or a laser range finder in relatively long or wide habitat units. Visual estimation techniques were used to determine substrate composition and fish cover types.

Mesohabitat Mapping

Habitat mapping of visually distinct habitat units on a reach-scale (referred to as mesohabitats) was used to estimate the overall quantity of aquatic habitat types available in the NFK, SFK, and UT. The mesohabitat mapping involved two main types of data collection and processing: field mapping and remote sensing analysis. Foot surveys were conducted within selected sample areas in the mainstem NFK, SFK, and UT in 2005 and 2007 to visually identify and delineate mesohabitat types (Table 15.1-1). Mesohabitat type definitions were based on Moore et al. (2006) and included run, riffle, pool, backwater, and beaver pond. Habitat unit lengths were measured using a laser range finder, and coordinates describing the upstream and downstream of each habitat unit were recorded using a handheld GPS unit.

For portions of each mainstem river that were not surveyed in the field, mesohabitats were mapped using remote-sensing data. Data sources utilized include 2004 ortho-rectified digital imagery of the NFK, SFK, and UT, 2008 ortho-rectified digital imagery of the UT, and 2004 geo-referenced videography from a low-flying helicopter of the SFK and UT. A series of steps were then undertaken in a GIS-software environment to be able to quantify the distribution of mesohabitat types within the NFK, SFK, and UT.

The first step involved using the 2005 and 2007 field data and a digitized channel margin layer to construct a polygon coverage describing mesohabitat units that were field surveyed. Habitat units delineated during field surveys were overlaid on the 2004 orthophotos and reviewed to calibrate the appearance of habitat types on the 2004 images. The second step was to expand the coverage of mesohabitat data. For portions of the mainstem rivers that were not surveyed, mesohabitat units were classified and delineated based on the 2004 imagery to create a polygon coverage for the remaining area. In addition, the 2004 videography and 2008 orthophotos were used to confirm habitat classifications and note temporal changes in habitats and channel locations. Lastly, the wetted area of all habitat unit polygons was calculated using a GIS function. The number of units and total area of each type of habitat was calculated for each EBD stream reach.

15.1.5.2 Fish Assemblage Surveys

Several studies were conducted annually from 2004 through 2008 in the mine study area to document and describe fish assemblage patterns in streams within the NFK, SFK, and UT watersheds and in the upper KR mainstem (Table 15.1-1). The studies included both extensive surveys to sample fish-bearing

waterbodies (e.g., mainstem rivers, tributaries, off-channel habitats, and lakes) within the mine study area, as well as several intensive studies to evaluate certain conditions (e.g., winter habitat use) or species behavioral patterns (e.g., the rainbow trout radiotelemetry study). In addition, adult salmon surveys were completed annually in all three watersheds to document the timing, distribution and abundance of salmon returning to these watersheds. Brief descriptions of methods used in completing these studies are provided below. More detailed descriptions are available in Appendix E of this EBD.

Fish Distribution and Relative Abundance Surveys

The 2004 through 2008 surveys document patterns of fish distribution, relative fish abundance, and fish density among habitat types (e.g., pool, riffle, run, etc.) within the NFK, SFK, and UT watersheds, and within the upper KR mainstem. Over the 5 years of study, there were 2,850 sampling units (discrete areas where fish were sampled) that were surveyed using a variety of fish sampling methods.

In general, the fish distribution and abundance surveys were completed using similar fish sampling, species identification, and life stage classification methods. The primary survey method for stream-dwelling fish was via direct underwater observation using snorkeling techniques (Northcote and Wilkie, 1963; Whitworth and Schmidt, 1980; Griffith, 1981; Griffith and Schill, 1984; Griffith et al., 1984; Hankin and Reeves, 1988). Other methods (e.g., electrofishing, minnow traps, beach seines, gill/tangle nets, angling, and dipnetting) were used when sampling conditions were not conducive to snorkeling (e.g., shallow water, fast water, deep water, and turbid water), or when there was a need to physically capture certain fish species for tagging and/or for genetic/toxicity sampling. Various fish sampling techniques applied during the fish studies are shown in Photos 15.1-2 and 15.1-3. To the extent possible, all fish observed and/or captured were identified to species and measured to fork length.

Coordinate data were collected using handheld GPS units to document fish observation locations. To describe fish abundance and density among habitat types, habitat data were collected at a subset of the fish distribution sampling locations, using either modified Tier 3 aquatic habitat survey protocols or anecdotal data collection, as described in the preceding aquatic habitat methods section.

Fish Use of Off-channel Habitats Study

Fish surveys were conducted in off-channel habitat areas in the NFK (2008), SFK (2005, 2006, and 2007), and UT (2007) watersheds (Table 15.1-1). To allow for a direct comparison between fish abundance and density in mainstem channel and off-channel habitats, mainstem channel habitats adjacent to the off-channel habitat areas were also surveyed as part of the off-channel habitat fish study. Snorkeling and electrofishing were the primary methods of sampling at both mainstem channel and off-channel sites, while other methods (e.g., minnow trapping, and seining) were used when site conditions precluded use of primary methods.

Winter Fish Surveys

Winter fish surveys were conducted in late October, November, and April at 157 sites in the NFK (2004, 2005, and 2006), SFK (2004 through 2007), and UT (2004 through 2007) watersheds, and in the upper KR mainstem in 2004 (Table 15.1-1). Winter fish sampling was generally limited, due to the iced-over and partially-frozen stream conditions from late fall through early spring that reduce the amount of open surface water available for sampling and that make sampling logistically difficult and risky. Furthermore,

this season in the mine study area is characterized by limited daylight hours and severe cold weather conditions presenting additional safety concerns for field crews and helicopter pilots. When sampling was conducted, site conditions, including open water surface area, ice thickness, and water depth, dictated the sampling techniques used at each site. Electrofishing and baited minnow traps were the primary survey techniques. Additionally, observations of fish were made through openings in the ice using direct observation, aided by aqua-scopes and face snorkeling. Sample sites were representative of mainstem, tributary, and off-channel habitats.

Mainstem Index Surveys

Mainstem index surveys were conducted in the mainstem NFK, SFK, and UT in 2004, 2005, 2007 and 2008. These surveys were designed to provide a snapshot of mainstem fish assemblages that would allow for comparison over time. Specifically, mainstem index surveys comprised of standardized and repeatable sampling at known locations in the mainstem channel of the NFK, SFK and UT to estimate the number of fish by species and life stage present and to provide an annual index of fish use in the mainstem that would be comparable over time and space. The 2004, 2005 and 2007 index sampling occurred at 12 pre-established mainstem index sites that were co-located with water quality and hydrology sites. Minnow traps were set for 24-hour periods in a variety of habitat types and captured fish were identified to species, enumerated, and measured. Sampling within these areas occurred repeatedly over the 2004 and 2005 survey years, allowing for temporal comparisons of fish assemblages. The 2008 surveys focused on 43 mainstem index sites established at 2.7-mile (4.3-kilometer [km]) intervals along the entire mainstem lengths of the NFK, SFK, and UT. Sampling included a full snorkel pass over the entire site length, as well as subsequent multi-pass beach seining. Modified Tier 3 habitat surveys (USFS, 2001) were completed to collect habitat data concurrent with the fish sampling and allow for comparison of fish assemblages across habitat types. Fish density by sampling method and habitat type were calculated and compared among habitat types.

Adult Salmon Surveys

Surveys to estimate the number of adult salmon spawning within the study area were initiated in 2004 and continued annually through 2008. These surveys were designed to document the spatial and temporal distribution of anadromous salmon returning to and spawning in the NFK, SFK, and UT watersheds, and to obtain estimates of spawning salmon abundance through direct observation. For this effort, aerial helicopter surveys were used to quantify spawning salmon throughout the entire lengths of the mainstem NFK, SFK, and UT, and in selected tributaries (Photo 15.1-4). The upper KR mainstem and Big Wiggly Lake, which is located on Tributary NFK 1.240, were also targeted for aerial surveys.

Differences in survey timing and frequency occurred among sampling years. For example, 2004 was the first year of baseline studies and seven aerial surveys were completed with a survey frequency of every 14 to 22 days. In contrast, surveys were conducted every 5 days in 2008 for 26 completed surveys. Otherwise, survey methods used were generally consistent among years. Surveys typically were conducted from early July through October or November to capture the range of dates adult Chinook, chum, coho, and sockeye salmon were present in the study area. Adult salmon were enumerated by species, and environmental conditions occurring during the surveys (e.g., weather, sun angle, glare, flow volume and depth, turbidity, stream bottom color, etc.) were recorded. A handheld global positioning system (GPS) unit was used to record the extent of each survey, and to mark areas of concentrated fish spawning, the upstream extent of salmon, and areas where environmental factors (e.g., ice cover, glare,

etc.) may have affected the counting process. Due to time and weather constraints, as well as helicopter availability, 2 to 3 days were typically required to cover the entire study area for each survey. In addition, aerial redd surveys were also conducted in 2004, 2005, and 2007. Redd locations were documented using a hand-held GPS unit.

Fish counts from aerial surveys are commonly used to estimate escapement of Pacific salmon species by watershed and year. Two common methods used for estimating salmon escapement are the area-under-the-curve (AUC) Trapezoidal Model (Neilson and Geen, 1981; Bue et al., 1998) and the Maximum Likelihood Estimation Model (Hilborn et al., 1999). Both of these models require assumptions about year- and stream-specific survey life and/or observer efficiency parameters. During the 2004 through 2008 study period, several attempts were made at determining site-specific values for survey life and observer efficiency. These attempts were unsuccessful at developing reliable estimates due to logistical constraints, such as low recovery of tagged fish on spawning grounds and physical stream conditions that affected the visibility of fish on reference videos. Without reliable estimates of observer efficiency and survey life, the utility of current escapement models is diminished (Holt and Cox, 2008). Furthermore, Holt and Cox (2008) present evidence that using the annual mean of survey counts is as good as, or better than, visual escapement models at illuminating trends in populations even when surveys have random spacing and high variability in frequency from year to year. For these reasons, a mean index count analysis, rather than an escapement analysis, was used to evaluate adult salmon abundance over the study period and among watersheds.

Index counts refer to the number of adult salmon observed on a given survey date. Annual mean index counts were calculated for each species by determining the mean of the index counts across the number of survey dates on which a species was observed. The subset of survey data included in the mean index count analysis was selected to allow for comparison of species-specific counts across watersheds and years. Thus, index counts from river reaches that were most consistently surveyed over the 5-year study period were used in the analysis. In order to maintain rigor in the analysis, it was also important to maximize the number of surveys included therein. Several surveys each year covered extended stream lengths and data within could not be parsed out by location; therefore, some variation in endpoints was allowed when selecting surveys for index counts. Surveys included by watershed are listed below.

- NFK—61 complete surveys that started at the confluence with the Koktuli River and ended near Big Wiggly Lake or at River Mile (RM) 34.78 (River Kilometer [RK] 55.98)
- SFK—67 complete surveys that started at the confluence with the Koktuli River and ended at the intermittent reach or at Frying Pan Lake
- UT—51 complete surveys that started at the mouth of the UT and ended at the confluence of Tributary 1.350 or at the headwaters

Inclusion of surveys with varied endpoints allowed incorporation of fish counts from upper reaches in all three watersheds, and although these data are diminished by comparison to overall counts, they add important information—especially for coho and sockeye salmon.

In addition to the mean index count analysis, an analysis of the spatial distribution and abundance of spawning salmon within each of the three major watersheds was conducted. Raw fish counts from 2008 surveys were used for this spawning distribution analysis, because spawning salmon locations were documented within each of the 18 pre-designated reaches in the NFK, SFK, and UT watersheds starting

that year. Reach-specific totals and mean numbers of spawning salmon for all survey dates were calculated for each species and were compared across reaches. All survey data collected in 2008 were included in the analysis.

Lastly, for each species, the 2004 through 2008 mean index counts were used to provide a first-order approximation of the relationship between counts in the NFK, SFK, and UT, and ADF&G's Bristol Bay fisheries statistics. Specifically, the Bristol Bay fisheries statistics considered were total inshore run estimates and commercial catch statistics for the Nushagak and Naknek-Kvichak districts (Morstad et al., 2010) and salmon escapement estimates for the Nushagak and Kvichak rivers (Baker et al., 2009). Although not directly comparable, the relative magnitude of the difference between the annual mean index counts and the Bristol Bay fisheries statistics will provide an indication of relative scale of the NFK, SFK, and UT runs compared to the runs into the larger river systems and respective commercial fishery districts.

Rainbow Trout Radio Telemetry Study

A rainbow trout radio telemetry study was conducted in 2007 and 2008 to investigate the seasonal distribution and migration patterns of adult rainbow trout in the UT and other streams associated with Iliamna Lake (Table 15.1-1). Radio transmitters were surgically implanted in 38 foraging fish captured between late August and mid-September 2007, and in 59 post-spawned fish captured between late-May and early-June 2008 (Photo 15.1-5). A combination of active (i.e. aerial) and passive (i.e. fixed) tracking was used to monitor fish movements (Photo 15.1-5). Fixed telemetry stations were positioned at the mouths of Lower Talarik Creek and the UT to provide continuous monitoring of transmitter movements as fish enter and exit the creeks. Mobile tracking surveys were conducted by fixed wing plane and/or helicopter. Survey frequency ranged from once per month from late fall through early spring (i.e., when fish are least active) to once per week from June through October (i.e., when fish are the most active).

15.1.5.3 Instream Flow Habitat Studies

A suite of interrelated instream flow habitat studies was conducted over the 5-year (2004 through 2008) study period. These studies are listed below.

- An assessment of habitat-flow relationships within the mainstem channel of the NFK, SFK and UT rivers
- An evaluation of off-channel habitats and their relationships to mainstem channel flow
- Defining water temperature and stream flow relationships within the mainstem channels
- An evaluation of flow and channel forming processes (collectively termed fluvial geomorphology) that included an assessment of spawning gravel characteristics as influenced by flow and salmon-induced physical disturbance

The methods associated with these studies are briefly described below, with more detail provided in Appendices 15.1C, 15.1D, 15.1E, and 15.1F.

Mainstem Channel Flow Habitat Studies

In 2004, instream flow habitat studies were initiated in all four watersheds in the mine study area (Table 15.1-1). The studies were completed using the United States Fish and Wildlife Service's (USFWS's) Instream Flow Incremental Methodology (IFIM), along with the companion suite of computer programs – **P**hysical **Hab**itat **Sim**ulation (PHABSIM; Bovee, 1982; Bovee et al., 1998) and were continued through 2008. The studies were designed to meet the objectives listed below.

- Describe existing mainstem channel habitats with regard to channel profiles, hydrology, and habitat conditions (e.g., habitat types, substrate, and cover)
- Define instream flow habitat relationships for target species at various life stages
- Based on the latter information, estimate the total amount of available habitat for target species at various life stages under baseline flow conditions in the mainstem channel of the NFK, SFK, UT, and upper KR mainstem

Application of PHABSIM in the watersheds followed the general procedures described in Bovee et al. (1998) and Milhous et al. (1984); field work was completed based on methods presented in Trihey and Wegner, (1981). The study involved the establishment of a series of transects (lines extending across the channel) within each stream located at different habitat types (e.g., riffle, run, pool, glide, cascade, and island complex; Bain and Stevenson, 1999), and the measurement of habitat characteristics (consisting of depth, mean column velocity, substrate type and/or cover) at intervals across the transects at different flows (Photo 15.1-6). Three distinct flow levels were targeted corresponding to a low-flow (representing approximately the 80 percent exceedence flow), mid-flow (representing the 50 percent exceedence flow), and high-flow (representing approximately 20 percent exceedence flow). These flow levels typically occurred in June, July, and August, respectively.

Transect locations were based on field reconnaissance surveys, topographic maps, and remote sensing data, as well as imaging and channel and habitat characteristics, professional judgment, and a stratified random approach. For studies conducted in 2004, 2005, and 2007, transect placement was designed to capture representative habitat types within reaches spanning the entire lengths of the mainstem NFK, SFK, and UT, the upper KR mainstem, and one of the major tributaries in UT. Transect placement was based on a combination of professional judgment and a stratified random sampling procedure. This approach resulted in the establishment of 92 transects, corresponding to 21 transects in the NFK, 28 in the SFK, 32 in the UT, five in the upper KR mainstem, and six in Tributary UT 1.190. An additional 46 transects were established in 2008 targeting specific areas of fish use, and to fill-in areas where no or few transects existed. The 46 transects were distributed within three NFK sites (14 transects), two SFK sites (12 transects), two UT sites (11 transects), and two tributary sites – one on NFK 1.190 (three transects) and one on SFK 1.190 (six transects).

Consistent surveying and data collection procedures, as outlined by Trihey and Wegner (1981), were used across sampling years. Physical and hydraulic measurements (e.g., channel profile and velocity data) were made at set intervals across each transect during targeted flow periods using a top setting rod and velocity meter. The flow and habitat data collected were subsequently used with PHABSIM programs to develop calibrated hydraulic models used to extrapolate hydraulic conditions beyond those measured in the field. The analysis presented in this section of the EBD pertains to 71 of the 92 transects established in 2004,

2005, and 2007 and the 46 transects established in 2008. Twenty-one of the original 92 transects were excluded from analysis due to a lack of sufficient model calibration data.

The hydraulic models were subsequently linked with Habitat Suitability Criteria (HSC) curves that represent the suitability of selected parameters (depth, velocity, and substrate/cover) for use by different life stages of the target fish species. The HSC curves for some species and life stages were based on existing literature-derived curves, while for others, field data were collected and site-specific HSC curves developed (Photo 15.1-7). The site-specific data consisted of depth, velocity, and substrate measurements made directly at observed fish locations as noted during snorkel surveys, as well as measurements made at distinct redds that represented spawning areas.

The draft HSC curves were linked with hydraulic and habitat models in PHABSIM to produce a series of habitat versus flow relationships by species and life stage for each transect. Appropriate versions of the USFWS microcomputer software (PHABSIM for Windows; v.1.20; PHABSIM DOS version) were used for all modeling analysis (Bovee and Milhous, 1978; Milhous et al., 1984; Milhous et al., 1989; Waddle, 2001). These relationships were linked with the mesohabitat mapping results and reach-specific hydrology data pertaining to a given species and life stage to produce both habitat time series and habitat duration curves for each of the main reaches in the NFK, SFK, and UT (Figure 15.1-6).

Off-channel Flow Habitat Studies

Off-channel habitats are defined as waterbodies located within a river's active valley, outside the mainstem channel. Off-channel habitats in glaciated river valleys are created by the interaction of channel processes, ground and surface water, vegetation, and beaver activity. The characteristics of many types of off-channel habitats, including their connections to mainstem channels, the relatively deep, slow-moving waters, and a mixture of woody debris and aquatic vegetation, make them especially attractive as refuge and rearing habitat for juvenile salmonid fishes. Therefore, studies were initiated in 2005 to assess the hydrological function of these waters in relation to the mainstem channels of the NFK, SFK, and UT. The studies resulted in the establishment and measurement of 37 transects that span representative off-channel habitat areas in the NFK (six transects), SFK (15 transects) and UT (16 transects) watersheds.

The off-channel transects were established at locations adjacent to or between the mainstem channel instream flow transects. Some off-channel habitat transects represented extensions of the actual mainstem channel instream flow transects from both ends into the floodplain. Transects were positioned perpendicular to the dominant flow and were approximately 1,000 feet (300 meters) long on either side of the mainstem channel. Physical and hydrological data along each off-channel habitat transect were collected at varying mainstem river flow levels. Data collection methodologies were designed so valley bottom profiles could be mapped and the variation in off-channel habitat water surface elevations (WSEs) could be linked to mainstem channel flow conditions. At each off-channel habitat encountered along the length of a transect, WSE at wetted edges was recorded, and water depths were measured so cross-section profiles of each habitat unit could be determined. Possible ground and/or surface water connections to the mainstem channel were noted. Mainstem channel WSEs associated with each off-channel habitat transect were also measured during the valley profile surveys. Photo 15.1-8 illustrates field data collection activities related to the off-channel habitat flow surveys.

Surveys of water connectivity were conducted in 2008 for the mainstem NFK, SFK, and UT to assess the hydrologic relationships between mainstem channel flow conditions and off-channel habitats. Potential

inlets and outlets to the mainstem channels were identified using aerial photos, topographic maps, and field surveys. For each identified hydraulic control point, WSEs and channel bed elevations were measured. Relationships between mainstem channel WSEs and bed elevations at hydraulic control points were used in conjunction with instream flow models to assess how flow changes might alter the availability of off-channel fish habitat. This assessment required an expansion of the measured to unmeasured areas within each system via ortho-rectified digital imagery and GIS analysis. Detailed methods are presented in Appendix 15.1D.

Water Temperature Monitoring and Modeling

Water temperature can affect a variety of salmonid species and their life history functions, including: the timing of adult upstream migrations and juvenile/smolt downstream migrations, the timing of spawning and duration of egg incubation, growth rates, and overall rates of survival (Quinn, 2005; McCullough et al., 2001; Sauter et al., 2001; Bjornn and Reiser, 1991). Temperatures in streams can vary hourly, daily, seasonally, annually, and spatially, with the degree of variation dependent on meteorological, topographical, and hydrological characteristics including patterns of runoff and groundwater exchange. Therefore, surface water temperatures were monitored in mine study area from 2004 through 2008 (Table 15.1-1). These data were subsequently used to develop and calibrate flow-sensitive surface water temperature models under these baseline conditions.

Surface Water Temperature Monitoring. Monitoring of surface water temperatures was initiated in 2004 and continued through 2008 at mainstem stations to collect baseline data on the existing surface water temperature regimes within the NFK, SFK, and UT systems (Chapter 7, Section 7.2; Photo 15.1-9). Continuous instream water temperatures have been measured at various locations and time periods since 2004 at intervals ranging from 1 minute to 2 hours, as described in Chapter 7.

Recorded water temperatures were compared to the Alaska Department of Environmental Conservation (ADEC) water temperature standards for the growth and propagation of fish, shellfish, other aquatic life, and wildlife (ADEC water temperature standards for aquatic life; ADEC, 2009). The ADEC water temperature standards for aquatic life depend on the type of fish habitat the station represents. According to these standards, the following life stage- and habitat-specific maximum temperatures may not be exceeded.

- Spawning areas, egg and fry incubation — 55ºF (13ºC)
- Migration routes, rearing areas — 59ºF (15ºC)
- At any time — 68ºF (20ºC)

Stream Network Temperature Model (SNTEMP). The USFWS SNTEMP (Version 3, revised in May 2005, after Theurer et al., 1984) was subsequently used to develop flow-sensitive surface water temperature models for each of the mainstem systems. Model documentation and detailed methodology are presented in Appendix 15.1E. SNTEMP is based on a combination of empirical and synthetic hydrological, meteorological, and stream geometry conditions. The model accounts for the physical processes of heat transfer and includes the following components.

- A heat transport model that predicts the average mean daily water temperature and the daily range in water temperature as functions of stream distance

- A heat flux model that predicts the energy balance between the water and its surrounding environment
- A solar model that predicts the solar radiation that penetrates the water as a function of latitude, time of year, and meteorological conditions
- A shade model that predicts the solar radiation-weighted shading resulting from both topography and riparian vegetation
- Meteorological corrections that predict changes in air temperature, relative humidity, and atmospheric pressure, as functions of a change in elevation

Fluvial Geomorphology and Spawning Gravel Quality

The fluvial geomorphology studies were initiated in 2005 and focused on describing channel geometry relationships and completing some preliminary hydraulic modeling in the SFK and UT (Table 15.1-1). Additional field data were collected in 2007 to describe the relationship between channel geometry and geomorphic processes in the NFK, SFK, UT, and upper KR mainstem (Table 15.1-1). Detailed data were collected at 52 Fluvial Geomorphology (FG) sites: 49 on the mainstem rivers and three on tributaries. Of the 49 mainstem sites, 15 were on the NFK, 16 on the SFK, 17 on the UT, and one on the upper KR mainstem. Two of the three tributary sites were in the SFK drainage and the third was in the NFK drainage. Data collected at each site included: information required for hydraulic modeling (based on based on the Hydraulic Engineering Center River Analysis System [HEC-RAS]), pebble count data (Wolman, 1954; Kondolf, 1997), site photographs, visual-based Manning's n roughness coefficient estimates, bank material composition, field notes, and qualitative estimates of bank vegetation type and density. The 2007 effort resulted in the identification of a characteristic discharge approximating bankfull flow conditions (Leopold and Maddock, 1953). The bankfull discharge is a representative parameter related to hydrologic and hydraulic conditions influencing channel form, primarily in alluvial channels.

The 2007 work also included collecting single bulk substrate samples at selected FG sites to begin assessing fine sediment levels in the river bed substrates. A radiotelemetry study of rock movement in the NFK was conducted in 2007 to evaluate riverbed mobility in more detail. Nineteen radiotagged rocks were deployed and monitored from September 15 through 30, 2007. In 2008, single bulk substrate samples were collected at additional FG sites and in sites containing spawning habitat (Photo 15.1-10). Replicate (three) substrate samples were also collected from nine sites (total samples = 54) within spawning habitat to statistically assess pre- and post-spawning fine sediment levels and to address the question of how the particle size distribution in known salmon spawning locations is affected by spawning fish, fall high flow events, and subsequent resorting of bed materials.

15.1.6 Results and Discussion

Existing aquatic habitats and fish resources within the NFK, SFK, and UT watersheds, and in the upper KR mainstem are summarized in this section. A discussion of the fish associations with available habitats and their known distributions throughout the study area, a synthesis of watershed processes and ecological influences on fish, and the relative contribution of fish in the study area to Bristol Bay fisheries are also included. As mentioned previously in Section 15.1.1, the data and graphics presented herein were selected as representative examples of the larger body of data (as presented in the detailed technical Appendices 15.1B through 15.1F and in other EBD chapters) as a way to provide readers with a summary

perspective of fish resource patterns in the mine study area. Readers interested in more detailed results than those presented here should refer to the technical appendices and/or other EBD chapters for more information.

Between 2004 and 2008, Pebble Project field crews conducted fish surveys at 2,850 distinct sites within the NFK, SFK, and UT watersheds (see fish location figures of specific watersheds in the subsections below). Data from sites where anadromous fish were documented were delivered to ADF&G as nominations to the State's Anadromous Waters Catalog (AWC). These data resulted in expansion of the known distribution of anadromous species and provided supporting information for existing anadromous streams (see anadromous fish distribution figures for specific watersheds in the subsections below).

Using the 2009 AWC as baseline, 22 new streams were nominated for the 2010 AWC — eight, five, and nine streams located in the NFK, SFK, and UT, respectively. The anadromous distribution was extended in an additional 14 streams, with five, two, and seven of those streams located in the NFK, SFK, and UT watersheds, respectively. The total lineal distance of nominated streams (new and extended distributions) was 23.1 miles (37.2 km). By watershed, the distribution of stream length nominated was 7.4 miles (11.9 km) in the NFK, 1.9 miles (3.1 km) in the SFK, and 13.9 miles (22.4 km) in the UT.

Sampling efforts at 1,260 sites located upstream of the documented anadromous fish distribution showed no anadromous fish present (see anadromous fish distribution figures for specific watersheds in the subsections below). For the purposes of the EBD, these sites have been considered as supporting only resident fishes. However, un-surveyed tributaries located upstream of the known anadromous fish distribution tributaries are assumed to have the potential to support anadromous fishes. Detailed maps of anadromous and resident fish presence at fish sampling sites are presented in Appendix 15.1B.

15.1.6.1 North Fork Koktuli River

NFK Watershed Overview

The NFK watershed is a relatively small drainage of the Nushagak-Mulchatna system. The Nushagak River Basin is one of eight river basins draining Southwestern Alaska into Bristol Bay (Figure 15.1-5). The NFK drainage is situated adjacent to the immediate vicinity of the Pebble Deposit (Figure 15.1-7). The NFK drainage area is approximately 113 square miles (mi^2; 292 square kilometers [km^2]) or 0.9 percent of the Nushagak-Mulchatna system and 0.3 percent of the entire Bristol Bay drainage basin (Table 15.1-2). The NFK includes an overall mainstem river length of 36 miles (58 km).

The NFK originates on the north slope of Groundhog Mountain, and generally flows west then southwest before joining the SFK to form the Koktuli River (Figure 15.1-7). The highest elevation in the NFK drainage is Groundhog Mountain (elevation 3,075 feet [937 meters]); the lowest elevation in the drainage is at the confluence of the NFK with the SFK at 580 feet (177 meters; Chapter 4). The watershed is bounded by a series of low, isolated mountain blocks — with Kaskanak Mountain to the south, Groundhog Mountain to the east, and Cone Mountain to the north. The northern surface water drainage divide is largely undefined.

A general map of fish resources study site locations in the NFK is shown on Figure 15.1-8. This map depicts 1,406 individual study site locations sampled between 2004 and 2008.

NFK Aquatic Habitat

This section describes the physical, chemical, and biological components of aquatic habitat documented in the NFK. These habitat components are discussed in distinct sections to facilitate comparison among watersheds.

NFK Physical Habitat Conditions

The mainstem NFK has been divided into six stream reaches with distinct hydrology, geology, and channel characteristics (Figure 15.1-7; Table 15.1-3). The six reach designations, NFK-A through NFK-F, progress from downstream to upstream along the length of the mainstem NFK. As discussed in Section 15.1.1, tributaries were assigned to the mainstem reach into which they flowed, and off-channel habitats were assigned to a mainstem reach based on their proximity to the mainstem channel. Photographs depicting representative channel characteristics of the mainstem NFK reaches are provided in Photos 15.1-11 through 15.1-16.

Channel Morphology. The NFK River is primarily a single-thread, gravel-bedded channel that is relatively straight in high gradient segments and meandering in low gradient segments. Channel slopes ranged from 0.09 to 0.80 percent and averaged 0.4 percent, as measured in the FG study sites. Tributaries were comprised of both high and moderate gradient, as well as alluvial fan channels. Large woody debris was scarce throughout the NFK due to a general lack of forest vegetation within the riparian zone. Large boulders deposited by retreating glaciers were sporadically located within the NFK channel and provided some instream cover, feeding station, and velocity shelter habitat for fish. The primary sources of sediment in the channel were likely from undercut banks and lateral erosion that occurred during high flows and ice break-up processes.

The three lowermost reaches (NFK-A, NFK-B, and NFK-C) flowed through primarily alluvial valley bottom deposits, consisting predominantly of abandoned stream terraces and deposits composed of re-worked glacial outwash. The stream channels within all three reaches were, overall, considered low gradient. High flows within NFK-A have overflowed the channel banks and extended into adjoining floodplains. Associated riparian zones, wetland complexes, and off-channel habitats extended well beyond the stream banks. For most of NFK-B, the channel flowed through a relatively narrow (approximately 1,525-foot; 465-meter wide) valley bottom bordered by low hills. NFK-C flowed across glacial outwash and moraine deposits. NFK-D and NFK-E were generally lower gradient than the other reaches and flowed through a variety of different geologic types, including glacial outwash and a silt, ice-rich section. Coarse bedload from upstream did not appear to have been transported downstream of NFK-E, where the bed was composed predominantly of sand and silt. The uppermost reach (NFK-F) flowed through predominantly alluvial and Brooks Lake drift deposits.

Hydrology. The surface water hydrology of the mine study area is described in detail as part of the Pebble Project EBD (Chapter 7, Section 7.2). The hydrologic regime of the NFK is influenced primarily by climate, geology, and groundwater influx, with stream flows driven by runoff from spring snowmelt and summer/fall rains. Except in losing reaches, base flows tend to remain high due to deep soils and associated groundwater storage, as well as the large volume of water associated with lakes in the watershed.

Seasonal flows in the NFK have two peaks (Figure 15.1-9), similar to other streams in Southwestern Alaska, and similar to the adjoining watersheds in the study area. The first peak occurs during the spring snowmelt season (with the majority of the snowmelt runoff typically occurring in May), while the second peak occurs during the fall rainy season (late August to November). These peaks are separated by two low flow seasons: a summer low flow (with minimum flows typically occurring in August), and a winter low flow (with minimum flows typically occurring in late March to late April) . The mean annual flow in the NFK was 270 cubic feet per second (cfs; 7.65 cubic meters per second [m^3/s]) during water years 2005 through 2008 at Hydrology Gage NK100A (USGS Gage No. 15302250). This discharge is equivalent to a mean annual unit runoff of 34.7 inches (88.1 centimeters) from the 106 mi^2 (274 km^2) watershed area at the gage.

Runoff was hydrologically flashy in steep NFK tributaries that drain the isolated mountain blocks where groundwater storage is limited. In contrast, the mainstem NFK showed a pronounced groundwater influence. Upstream from the upper two-thirds of NFK-C, the river has been classified as a "losing" stream. In this area, the NFK flows across unconsolidated outwash fan sediments with a high infiltration capacity, and water generated by stream flow, precipitation, and snowmelt rapidly infiltrates into a shallow aquifer (Chapter 7, Section 7.2). The groundwater flows down valley, emerging at the downstream end of the glacial outwash deposits. The downstream third of NFK-C, and a short stretch of NFK-B, were "gaining" reaches that exhibited evidence of substantial groundwater upwelling (Chapter 7, Section 7.2 and Chapter 9, Section 9.1). Similarly, the downstream portion of NFK-A (downstream from Hydrology Gage NK100A) received groundwater inflow increasing the local surface water discharges at these locations. The hydrologic regime of the NFK has an influence on the functionality and usability of fish habitat and, in turn, the distribution and abundance of fish that use the watershed.

Water Temperature. Water temperature data indicate that the NFK begins to seasonally warm in May and June and peaks in July and August. Temperatures cool down during September and October and stay near freezing from November through April. A series of temperature plots during calendar year 2007 at select NFK gages is shown on Figure 15.1-10 to indicate the general thermal regime across the watershed. More detailed temperature data, as well as a description of the SNTEMP flow-sensitive surface water temperature models that were developed and calibrated using these baseline data, are included in Appendix 15.1E.

The longitudinal thermal regime of the NFK was characteristic of a surface water system influenced by groundwater and coldwater tributary inflow (Figure 15.1-11). In most streams, water temperatures during the summer months (June, July and August) are expected to increase in the downstream direction because air temperatures increase with decreasing elevations. However, the NFK exhibited the opposite trend, with warmer temperatures found in the uppermost reaches (NFK-E and NFK-D) and cooler temperatures downstream at reaches NFK-C, NFK-B, and NFK-A. In 2007, mean daily summer water temperatures declined approximately 36 degrees Fahrenheit (ºF; 2 degrees Celsius [ºC]) in the mainstem between reaches NFK-D and NFK-C, immediately downstream of the confluence with Tributary 1.190 (Figure 15.1-11). Temperatures continued to decline downstream through the length of both NFK-C and NFK-B. Water temperatures, combined with flow records, indicated that the NFK receives groundwater inflow in NFK-C and in portions of NFK-B and NFK-A (downstream from Hydrology Gage NK100A). The groundwater input keeps the surface water temperatures relatively cool in the summer, and relatively warm in the winter.

While water temperatures have been at or near freezing during the winter season throughout most of the stream, there was greater variability in water temperatures during the summer (Appendix 15.1E). The daily temperature range during the summer months for all monitoring gages and years for the NFK watershed is provided in Table 15.1-4. The instantaneous minimum and maximum daily temperatures ranged from a low of 33ºF (0.3ºC) at monitoring site NFK119WT in Tributary 1.190 during 2008 to a high of 71.4ºF (21.9ºC) at monitoring sites NK100C in 2005 and NK100A1 in 2007.

Instantaneous summertime maximum temperatures exceeded the ADEC maximum water temperature standard for aquatic life of 68ºF (20ºC; ADEC, 2009) at one station (NK100C) in 2004 through 2007 and at station NK100A1 in 2007 (Table 15.1-4), representing 28 percent of the total summer maximum temperature recordings. The ADEC maximum water temperature standard for spawning and egg and fry incubation of 55ºF (13ºC; ADEC, 2009) was exceeded for 89 percent of the instantaneous station measurements, whereas the ADEC maximum water temperature standard for migration routes and rearing areas of 59ºF (15ºC; ADEC, 2009) was exceeded for 78 percent of the measurements of the summer maxima recorded during the study period. Anadromous salmonid fishes migrate and spawn in various NFK reaches during July and August. Thus, these summer temperatures naturally exceed state water quality numeric standards.

The thermal regime of the NFK has an influence on the behavior, metabolism, and growth of fish and their use of specific habitats. In the study area where freezing and low water temperatures are a concern, fish would likely be attracted to groundwater-fed channels during winter and early spring, because these sites represent areas of stable flows and relatively warmer water temperatures (Leman, 1993; Ebersole et al., 2003). Groundwater inflow offers temperature moderation in both the mainstem and tributary reaches in winter, such that a portion of these areas remain ice-free (Chapter 7, Section 7.2, Figure 7.2-5). These areas may provide overwintering habitat that is often limited in northern streams, and as such, enhance the survival of incubating embryos compared to frozen stream sections.

The annual water temperature regime of the NFK is cold, severely restricting rearing conditions. Because fish are cold-blooded species (cannot regulate their body temperature) all metabolism, activity, swimming speed, and behavior are directly a result of ambient water temperature conditions. Cold water restricts active feeding to a brief period (June through September) when water temperatures exceed 46ºF (8ºC) and hence productivity of the population is limited compared to watersheds where the active feeding period is longer (Campbell and Neuner, 1985). Notably, in this cold water river, warm water temperatures in the summer months also may be limiting to fish health and productivity. Given the open riparian nature of most of the streams in the NFK watershed, water temperatures warm quickly during the summer months and naturally have exceeded state thermal criteria for spawning, incubation, migration, and rearing habitat at a number of monitoring stations (Table 15.1-4).

Mainstem Channel Habitat. The baseline frequencies of mesohabitat types (e.g., pool, riffle, run/glide, etc.) for the mainstem NFK are shown on Figure 15.1-12. Riffle habitat was the dominant habitat type in NFK-A, B, C and D, with run/glide as a subdominant habitat feature. In NFK-E, beaver ponds, riffles, and glides were the most common habitat types. Pool habitats were relatively sparse (1 to 2 percent) in all mainstem NFK reaches. The frequency of USFS channel types along Tributary 1.190 and the results of Tier 3 field surveys are shown on Figures 15.1-13 and 15.1-14, respectively. Channel type codes are listed in Table 15.1-5. In general, all of the habitat studies indicate that the NFK overall contained mostly riffle habitat, followed by varying degrees of run and glide habitat, and relatively few beaver ponds and pools.

In addition, relatively small amounts of cascades and backwater/sloughs were observed in NFK 1.190 during the Tier 3 aquatic habitat surveys (Figure 15.1-14). As noted above, large woody debris was generally absent within the NFK due to a lack of forest vegetation in the riparian zone. As a result, instream cover for fish was largely provided by undercut banks and overhanging vegetation, along with scattered boulders and cobble materials.

Pacific salmon require cold, clear, and well oxygenated water with gravel- to cobble-sized substrates for spawning. The quality of spawning gravels in the NFK was good, based on grain size analysis of bulk substrate samples collected from three locations. The levels of fine sediments in samples collected from the NFK were lower than levels found in both the SFK and UT. Overall, the concentrations of size fractions that have been related to embryo survival (size fraction less than 0.03 inches or 0.84 millimeters) and fry emergence (less than 0.25 inches. or 6.4 millimeters) were well below levels considered harmful (over 10 percent and over 20 percent, respectively; after Shirazi et al., 1981; Lotspeich and Everest, 1981; Chapman and McLeod, 1987; Reiser and White, 1988; Kondolf, 2000). See Appendix 15.1F for detailed results of the spawning gravel analysis.

Off-channel Habitat. The off-channel habitat study area in NFK-C contained an estimated 32 acres of off-channel habitat (Table 15.1-6). The most frequently encountered type of off-channel habitat was beaver ponds (85 percent; Figure 15.1-15). Complex beaver ponds typically include a combination of ponded areas and connecting channels that create both pool and slow moving run/glide type habitats. With the exception of isolated ponds that are only connected to the mainstem channel during overbank flows, off-channel habitats can potentially be used by a diverse assemblage of fish species and life stages at a range of mainstem channel flows. Survey results indicated that many of the off-channel habitats were hydrologically connected to the mainstem channel via surface inflow at less than bankfull flows (approximately 580 cfs [16.4 m^3/s]; Appendix 15.1D). A subsample of 11 off-channel habitat sites showed engagement of sites at flows ranging between 14 and 490 cfs (0.4 and 13.9 m^3/s; Table 15.1-7). See Appendix 15.1D for more information regarding the off-channel habitat flow study.

NFK Chemical Habitat Conditions

A comparison of various water quality parameters reported in the mine study area and those reported for other water quality studies in the region is provided in Table 15.1-8. These parameters include water temperature, dissolved oxygen (DO), specific conductance, pH, turbidity, alkalinity, and hardness. The NFK watershed was characterized by generally good water quality conditions that support habitat conditions for a range of salmonid and non-salmonid fishes. Overall, the NFK water quality parameters measured were similar to those for other watersheds in the region (Table 15.1-8). The notable exceptions include: a maximum water temperature of 66.2ºF (19.0ºC), which is greater than those reported for other watersheds (excluding the SFK); a low DO minimum of 5.8 milligrams per liter (mg/L); and a broader range of reported values for pH, alkalinity, and water hardness. Concentrations of water quality parameters were found to vary as a factor of flow conditions, location within the watershed, or season (Chapter 9, Section 9.1).

In addition to the water quality parameters included in Table 15.1-8, concentrations of trace elements, cyanides, and nutrients were determined as part of the surface water quality studies in the mine study area (Chapter 9, Section 9.1). Natural exceedences of estimated freshwater aquatic life criteria were observed in the NFK for aluminum (total), cadmium (total and dissolved), copper (total and dissolved), iron (total), lead (total and dissolved), zinc (total), and weak acid dissociable (WAD) cyanide. The number of samples

exceeding these criteria was less than 1 percent for dissolved cadmium, total zinc, and total iron, less than 2 percent for dissolved copper, less than 3 percent for total cadmium, total copper, and WAD cyanide, less than 7 percent for total aluminum, and less than 8 percent for dissolved lead. The greatest number of CALC exceedences was for total lead (approximately 15 percent). The majority of the total aluminum exceedences occurred in April and May and thus, may be related to seasonal snowmelt events. No pattern was evident for lead exceedences, which occurred in various months and locations. Mean nutrient concentrations were generally low.

NFK Aquatic Macroinvertebrates

The productivity of streams is often measured in terms of the number and composition of species, and the density and/or abundance of periphyton and aquatic macroinvertebrates. Periphyton represents a broad assemblage of algae, bacteria, and other microscopic organisms that are attached to rocks, logs, and other submerged materials. The periphyton community often forms the food base for the aquatic macroinvertebrate community that is comprised of a mixture of organisms, including: nematodes, annelids, crustaceans, flatworms, mollusks, and insects. Insects are the most species-rich, and often most abundant group of benthic macroinvertebrates residing in freshwater habitats (Hershey and Lamberti, 2001; Ward, 19992). Macroinvertebrates are involved in the recycling of nutrients and decomposition of organic materials, serving as a conduit for the energy flow from organic matter resources to vertebrate populations, most notably fish (Hershey and Lamberti, 2001; Hauer and Resh, 1996). Studies of both communities have been conducted in the NFK and detailed results are described in Section 15.2. Because of the importance of macroinvertebrates as both food for fish and as indicators of stream health, annual results of the macroinvertebrate studies in the NFK are summarized for June sampling efforts below.

The macroinvertebrate taxa richness (i.e., the number of taxa present) of two sample sites (NK-100A and NK-100C) is shown on Figure 15.1-16. Taxa richness was determined for June sampling efforts in 2004, 2005, and 2007 using two different collection methods: the Alaska Stream Condition Index (ASCI) kick net and Surber methods. Taxa richness ranged from a low of 17 taxa at NK-100A in 2005 (Surber method) to a high of 30 taxa at NK-100C in 2007 (Surber method; Figure 15.1-16). Taxa richness was generally consistent among years for both sites, although taxa richness was slightly greater at NK-100C than NK-100A.

The macroinvertebrate communities in the NFK were largely composed of midge larvae (Family Chironomidae) and invertebrate species of the orders Ephemeroptera (mayflies), Plecoptera (stoneflies), and Trichoptera (caddisflies; EPT taxa). The contribution of chironomids ranged from 36 percent at NK-100C in 2005 (Surber method) to 76 percent at NK-100A in 2005 (ASCI method; Figure 15.1-16). For EPT taxa, percentages ranged from 7 percent at NK-100C in 2007 (ASCI method) to 29 percent at NK-100C in 2005 (Surber method; Figure 15.1-16). The macroinvertebrate communities at both sites were dominated by chironomids in all years.

NFK Habitat/Flow Relationships

This section presents the results of instream flow habitat modeling and time series analyses computed for various salmonid fish species for each of three NFK reaches (NFK-A, NFK-B, and NFK-C) and one tributary (NFK 1.190). No results are displayed for NFK-D, NFK-E, and NFK-F, because transects were not established in those reaches. NFK-D and NFK-E contain smaller amounts of spawning habitat than the three downstream reaches, and no spawning activity has been reported in NFK-F. Thirty (30) transects were used in the analysis (Table 15.1-9): 13 in NFK-A, five in NFK-B, nine in NFK-C, and three in

Tributary NFK 1.190. Transect weightings based on the frequency of representative habitat types in a reach are summarized in Table 15.1-10.

Specific flow ranges corresponding to 90 percent or more of the maximum modeled habitat areas in each reach are shown for anadromous and non-anadromous fish categories in Table 15.1-11. The ranges vary as a factor of the results from different species as reported in Appendix 15.1C, Tables 28 to 36.

Results of the habitat time series analyses for Chinook, coho, and sockeye salmon spawning and juvenile life stages are summarized for NFK-A, NFK-B, and NFK-C on Figure 15.1-17. These results focus on the total habitat area versus river flow relationships, because this parameter provides reach-scale estimates of the total amount of habitat for a given species and life stage available under different flow conditions (refer to Appendix 15.1C for tributary results, other flow related parameters, and individual transect results). The results, expressed in acres, are presented graphically as a time series of habitat based on average flow conditions in the reaches. The time series analyses are presented graphically by reach in terms of the total habitat area that would occur on a daily basis during the time period in which an individual species and life stage may be present. For example, juvenile Chinook salmon may be present year-round, while adult spawning is limited from July through September, as depicted on Figure 15.1-17. This evaluation is useful for comparing the relative amounts of habitat provided for a given species and life stage under different flow conditions.

The total estimated amount of habitat area (spawning and juvenile) for each species available within a given reach, based on the median daily flows over the respective time periods for each life stage, is displayed on Figure 15.1-17. The results indicate there can be substantial variability in habitat amounts on a daily basis in response to changes in flow. This variation is most evident during flow transitional periods. For example, during the spring-summer periods when flows are declining there is a general increase in juvenile habitat. Similarly, during the summer-fall periods when flows increase, there is a general increase in spawning habitat. The overall process used in deriving the time series and the detailed results for these species, as well as other species and life stages (includes species and life stage habitat-flow relationships), and for Tributary NFK 1.190, are presented in Appendix 15.1C.

The time series analysis represents a first step in evaluating how baseline flow conditions influence fish habitats temporally and spatially. Additional time series analyses based on wet year, dry year, and average year conditions, as well as a series of associated habitat duration curves for each reach, are provided in Appendix 15.1C, Tables 30, 33, and 36, and Figures 31 through 33, 37 through 39, and 43 through 45. The appendix also contains estimates of total habitat area by species and life stage provided in the entire NFK (all reaches combined) during an average water year (Appendix 15.1C, Table 73).

NFK Special Habitat Features

Special habitat features that may influence the distribution and/or abundance of fish within the NFK watershed include seeps and springs, intermittent flow reaches, lakes and ponds, and beaver ponds.

Seeps and Springs. A comprehensive survey of seeps and springs was performed in 2005 and 2006, and the surface water expression of these features is presented in Chapter 9, Section 9.1, Figure 9.1-4. There was a large concentration of seeps and springs identified in the central portion of the NFK (along the upper portion of NFK-B and throughout NFK-C), southward to the boundary between the NFK and SFK

at Kaskanak Ridge, and throughout the Tributary NFK 1.190 subwatershed. Seeps and springs add to river flow and moderate stream temperatures in both summer and winter.

Such surface water expressions may offer groundwater upwelling sites salmonid fishes favor for spawning locations. Mainstem NFK-B and NFK-C and Tributary NFK 1.190 have been used for spawning by anadromous fishes (see the Fish Resources section below). These stable, cool water sources likely provide benefits to juvenile fishes during summer rearing. In the winter, seeps and springs may create localized areas of relatively warmer water that may be used as overwintering habitats and may promote higher salmonid embryo survival.

Intermittent Flow Reaches. There were no mainstem NFK reaches temporarily exhibiting seasonal surface water flow cessation during the 2004 through 2008 baseline period (Chapter 7, Section 7.2, Figure 7.2-5). Conversely, Tributary NFK 1.190.10 exhibited late summer intermittent flow conditions, immediately upstream of its confluence with Tributary NFK 1.190. The total length of dry stream channel in this tributary was slightly more than 2 miles (3.2 km).

Lakes and Ponds. Naturally-formed lakes and ponds are prevalent in the NFK watershed, consistent with the remnants of the glacial history. The largest named lakes in the watershed include Big Wiggly and Black lakes (Figure 15.1-7; see Appendix 15.1G for waterbody naming conventions). Most of the lakes and ponds in this watershed occur at relatively high elevations. The largest concentration of lakes and ponds is in the vicinity of the Big Wiggly Lake complex, adjacent and connected to NFK-D. Sockeye salmon adults have been recorded spawning along the lakeshore of the Big Wiggly complex of lakes and rearing of juvenile sockeye salmon in lakes is a critical life-history strategy (see Fish Resources section below). Surface water impoundments of this nature also provide habitat for other stream-dwelling fishes and provide water storage and extended surface water runoff volumes late in the summer period compared to watersheds without such storage.

Beaver Ponds. Beavers were ubiquitous throughout the NFK and, in some locations, have had a considerable effect on flow and habitat conditions. Analysis of aerial photos indicates that beavers have built dams spanning the mainstem channel in the headwaters of the NFK (see Appendix 15.1F). Such structures result in the ponding of water that creates a mosaic of small ponds and interconnecting channels. During wildlife surveys in the NFK, 25 beaver colonies were recorded (Chapter 16, Section 16.2, Figure 16.2-20). Beaver ponds in the NFK provide adult spawning and juvenile overwintering habitat for Pacific salmon. Coho salmon were reported spawning in beaver-created habitats in the NFK watershed. Beaver ponds and small stream channels influenced by groundwater, may provide ice-free habitat during winter (Murphy et al., 1989; Collen and Gibson, 2001). In addition, beaver ponds in the NFK were slightly warmer than other habitat types and thus, may represent a more productive habitat as compared to cooler mainstem channel habitat types. This may result in increased growth rates of juvenile salmon and more fish per unit area compared with mainstem channel fish (Appendix 15.1D).

NFK Potential Limiting Factors

Habitat features in either short supply or in poor relative condition that may be limiting fish abundance and productivity in the NFK are discussed below.

Velocity Shelter. A general scarcity of mainstem channel pool habitat and instream cover features in the NFK results in a lack of velocity shelter for rearing fishes. This condition suggests juvenile rearing may largely be relegated to off-channel habitats, especially for winter refuge when water temperature and

stream flows become quite low. The lack of juvenile winter rearing habitat in the mainstem NFK was evident in the instream flow habitat duration curves (Figure 15.1-17).

Water Temperature. The annual water temperature regime of the NFK is cold, and largely restricts rearing conditions (i.e., period of active feeding and growth) to a relatively short period of time (June through September) when water temperatures exceed 46ºF (8ºC). This is because fish are cold-blooded species (cannot regulate their body temperature) and many of their metabolic functions, including growth and other physiological processes, are linked to ambient water temperature conditions. Therefore, the overall productivity of the fish populations is likely limited as compared to watersheds with warmer water temperature regimes and where the active feeding period is longer (Campbell and Neuner, 1985). This limitation is likely typical of other regional streams.

Notable in this cold water river is the fact that warm water temperatures in the summer months also may be limiting to fish health and productivity. Given the open riparian nature of most of the streams in the NFK watershed, water temperatures warm quickly during the summer months and naturally exceed the ADEC maximum water temperature standard for spawning and incubation of 55ºF (13°C; ADEC, 2009). Exceedences represented 89 percent of the instantaneous station records reporting peak summer temperatures (June through August) during the baseline period. Temperatures also exceeded the ADEC maximum water temperature standard for migration routes and rearing areas of 59ºF (15°C; ADEC, 2009) for 78 percent of the summer records, and the ADEC maximum water temperature standard of 68ºF (20°C; ADEC, 2009) for 28 percent of the peak recorded summer temperature values over the baseline period. The recorded high temperatures in the NFK are several degrees higher than those reported for most other streams in the region (Table 15.1-8).

Water Quality. Water quality data indicate the waters of the NFK are soft (Chapter 9, Section 9.1). Soft waters are typically not as productive for fish growth as hard (more mineralized) waters. Low levels of mineralization can influence aquatic productivity, including fish biomass, in comparison to streams with high levels of mineralization (McFadden and Cooper, 1962; Hendrickson et al., 1973; Marshall et al., 1980). Thus, hardness and similar measures of mineralization (e.g., alkalinity, TDS, conductivity, etc.) can be used as screening level surrogates for stream productivity. This limitation is likely typical of most regional streams as summarized in Table 15.1-8.

Soft waters can also increase the acute toxicity of divalent trace metals to aquatic organisms. Toxicity increases inversely to water hardness (Carroll et al., 1979; Pagenkopf, 1983; Pascoe et al., 1986; Davies et al., 1993; Markich and Jeffree, 1994; Meyer et al., 1999). Pagenkopf (1983) provides evidence suggesting metal toxicity to fishes is a function of divalent trace metal attachment to gill surfaces. Markich and Jeffree (1994) and Meyer et al. (1999) imply as hardness increases, divalent calcium ions will bind to the gill surface in lieu of further metal attachment. Thus, metal toxicity is reduced in hard waters compared to soft waters. Chronic Aquatic Life Criteria (CALC) in Alaska waters for various trace metals are a function of hardness concentrations (ADEC, 2008). Based on water quality data collections for trace metals in the NFK, aluminum, cadmium, copper, iron, lead, and zinc occasionally exceeded estimated CALCs (Chapter 9, Section 9.1). Of these six metals, all but the aluminum and iron criteria are a function of water hardness. Given the low frequency and limited geographical extent of criteria exceedences, the baseline water quality conditions for trace metals are not regarded as a potential limiting factor to fish production in the NFK. However, the soft waters remain a risk to increased metal toxicity from cadmium, copper, lead, and zinc. Lead has a much higher frequency of exceedences than the other constituents in

the NFK, but is not considered a potential natural limiting factor to fish production since the exceedances are not seasonally or spatially correlated. Rather, the exceedances are spread throughout the year and basin suggesting no long term chronic exposure to fish. Of the 34 total lead exceedances, there were only seven instances with exceedances ocurring in consecutive months and no locations had exceedances ocurring more than two months in a row.

Generally, nutrient concentrations in the NFK were found to be low (Chapter 9, Section 9.1). The production of primary producers is based on a combination of sunlight, temperature, and nutrient availability. At any point in time, one of these factors will limit aquatic productivity. If the availability of nutrients is the concern, the current ratio of nitrogen to phosphorus suggests nitrogen would typically be the limiting nutrient for growth of photosynthetic organisms in the NFK. Should productivity of primary producers become reduced, based on a lack of nitrogen, it is likely secondary consumers and, ultimately, food resources for fish species may become reduced compared to other regional streams.

Stream Flow. Intermittent stream flows are generally not a concern along mainstem channels in the NFK. However, reduced flows in some of the tributaries could potentially limit fish production on a local level. For example, Tributary NFK 1.190.10 routinely exhibited late summer intermittent flow conditions, immediately upstream of its confluence with Tributary NFK 1.190. The total length of dry stream channel in this tributary was slightly more than 2 miles (3.2 km).

Groundwater. Surface water expression of groundwater can provide considerable benefits to spawning and rearing fish. Although the zones of observable groundwater influence are widespread in the NFK, there are areas in the mainstem channel where groundwater influx was not prevalent. Fish abundance and productivity might be reduced in these locations compared to areas of high groundwater input. As an example, chum salmon spawning was conspicuously absent in the middle portion of NFK-A (Appendix 15.1B, Figure B.1-10). This location is upstream of the zone of major groundwater influx to surface waters in the reach.

Potential limiting factors will vary for each species and life history stage. For example, anadromous salmonid species with extended freshwater residence time like Chinook, coho, and sockeye salmon, as well as resident salmonid fishes, are typically considered limited by the juvenile rearing life stage. Conversely, species with abbreviated residence time, like chum salmon, are considered spawning-limited in the stream environment. Based on the itemized list of limiting factors above, it is likely the most limiting life-history stage for most of the species is juvenile overwinter rearing.

For chum salmon in the NFK, the abundance and productivity of populations is limited by the amount of viable spawning habitat. Spawning habitat may be restricted, in part, due to the distribution of spawning gravels, as well as the hydrologic regime and groundwater inputs to areas downstream of NFK-D.

NFK Fish Resources/Assemblage

At least 13 different fish species were documented in the NFK from 2004 through 2008 (Table 15.1-12). This count is a minimum number, because certain resident fishes including sticklebacks, sculpin, and whitefish, were not consistently identified to species during field surveys. Overall, the greatest number of fish species (13) was found in NFK-C, and there was a general tendency for the number of species to decrease in reaches further upstream (Figure 15.1-18). Only three species groups were found in NFK-E (coho salmon, Dolly Varden, and sculpin) and NFK-F (Chinook salmon, Dolly Varden, and sculpin). In

general, the species composition found during the baseline period was similar to that documented by reconnaissance field efforts in the early 1990s (Buell, 1991). Buell's field effort documented all but two of the species (rainbow trout and chum salmon) that were collected during the EBD studies. Both of these species were located in small numbers in the lower mainstem NFK (reaches NFK-A through NFK-C). Buell's sampling in the mainstem NFK was limited to four off-channel sites sampled on a single date, as compared to multiple and repeated sampling throughout these reaches during the 2004 through 2008 study period (Figure 15.1-8). Thus, it is reasonable to have some variation in the species encountered.

The life stage periodicity (reflecting the timing of various life stage functions — spawning, egg incubation, fry, juvenile, and adult migration) for anadromous and non-anadromous salmonids is presented on a regional basis in Appendix 15.1A and on a fish study area basis on Figure 15.1-19. Figure 15.1-19 was developed based on a general understanding of local fish populations and refers to the general timing of fish life history stages for the entire aquatic resources study area (Appendix 15.1C). Life history information specific to the NFK watershed is included in the species descriptions below and in Appendix 15.1A.

Many fish species present in the NFK are important to commercial, subsistence, and recreational harvest. Anadromous salmonid fishes from the NFK, along with those from the Wood, Snake, and Igushik rivers and the Nushagak watershed downstream of the NFK, are considered part of the Nushagak Management District. Because no data are available to assess the relative contribution of these NFK fish to the fisheries, district-scale data are provided here as an indication of the importance of these fisheries. Based on a 20-year average (1988 through 2007), the annual commercial harvest for the overall Nushagak District was 52,190 Chinook, 476,508 chum, 28,660 coho, and 4,969,524 sockeye salmon (Jones et al., 2009). Over the same period, the average annual subsistence harvest for the overall Nushagak District was 13,047 Chinook, 4,461 chum, 5,420 coho, and 26,421 sockeye salmon.

In general, recreational harvest of anadromous salmonids is considerably less than commercial and subsistence harvest. NFK salmon are a part of the Bristol Bay Sport Fish Management Area. In the Bristol Bay Sport Fish Management Area, the average annual recreational harvest for the 2000 to 2004 time period was: 10,067 Chinook, 2,108 chum, 13,611 coho, and 12,288 sockeye salmon (Dye et al., 2006). Over the same period, the average annual recreational harvest in the Mulchatna River, into which the NFK eventually drains, was 194 Chinook and 160 sockeye salmon. Data specific to recreational harvest in the NFK are not available; however, it can be assumed that the number would be less than that for the Mulchatna River system.

The following sections describe the fish resources in the NFK by species assemblages under major grouping of anadromous salmonid fishes, non-anadromous (resident) salmonid fishes, and non-salmonid fishes. Data are presented in terms of mainstem channel reaches, off-channel habitat, and tributary waters draining into the mainstem reaches in the NFK. Many of the sampling techniques were not conducive to estimating catch-per-unit-of-effort (CPUE), but where sufficient electrofishing or snorkeling data exist from all survey passes, the species assemblages including collections of all life history stages indicate the trends presented in Table 15.1-13.

Furthermore, fish survey results are commonly discussed below using relative fish abundance and fish density metrics. The relative abundance metric, which is expressed as the total number of fish encountered per 328 lineal feet (100 meters), is used to describe fish assemblages throughout the watershed and among habitat types. This metric was calculated for each species by summing the total

number of fish observed or captured within a given habitat type and dividing it by the total lineal distance, in meters, of the habitat type surveyed; this metric was then multiplied by 100 such that the abundance metric is standardized to 100 meters or 328 feet. The fish density metric, which is expressed as the number of fish per 1,076 square feet (sf; 100 square meters [m^2]), is used to assess fish-habitat associations and allows for a direct comparison of fish numbers among habitat types. The fish density metric was calculated in a manner similar to the abundance metric, with habitat area (wetted width times sample length) used in place of sample length. The associated relative fish abundance and fish-habitat association figures represent a summary of the mainstem channel fish abundance and density figures presented in Appendix 15.1B. In Appendix 15.1B, these metrics were calculated separately for the 2004 through 2007 and 2008 study years, as well as for mainstem and tributary habitats. In the Section 15.1 relative abundance and fish-habitat association figures, only mainstem channel data are reported, and the metrics have been calculated by combining the 2004 through 2007 and 2008 data.

NFK Anadromous Salmonid Fishes

Anadromous salmonid fishes were the most abundant fish taxa encountered in the NFK watershed. The distribution, life history, spawning abundance, relative abundance, and habitat associations of each of the four (Chinook, chum, coho, and sockeye salmon) anadromous salmon species present in the NFK are discussed in the following sections. The presence of anadromous fish species in the six NFK reaches, as determined from 2004 through 2008 survey data, is shown in Table 15.1-14. The distribution of anadromous fishes throughout the NFK watershed based on data from 2004 through 2008, as well as the ADF&G anadromous stream layer, is depicted on Figure 15.1-20. Anadromous spawning locations throughout the NFK watershed are depicted on Figure 15.1-21, while specific spawning locations for each species and reach are provided in Appendix 15.1B.

Chinook Salmon. Chinook salmon (*Oncorhynchus tshawytscha*) were observed in all NFK reaches, with the exception of NFK-E (Table 15.1-14; Figure 15.1-18). The numbers of Chinook salmon tallied during the study period upstream of the confluence of Tributary 1.190 and NFK-C were relatively low compared to those in NFK-A, NFK-B, and NFK-C. Only four juvenile fish were observed in NFK-F in 2008, and eight juveniles and three adult carcasses were observed in NFK-D (Appendix 15.1B). Greater than 50 adults and 14,000 juveniles were observed in NFK-A, NFK-B, and NFK-C combined during on-the-ground surveys during the baseline study period.

Chinook salmon juveniles were present year-round in the NFK study area.In general the life history of Chinook salmon is for fry to emerge from redds in spring and stay in the watershed until outmigration to the ocean. While juveniles in some populations out-migrate as young-of-the-year fry, this life history pattern is uncommon in the Bristol Bay basin (Appendix 15.1A). Based on length frequency distributions, three age classes of juvenile Chinook salmon have been observed rearing in the NFK: young-of-the-year/subyearlings (0+), yearlings (1+), and 2+ age juveniles. The mean length of these Chinook salmon by age-class, is shown on Figure 15.1-22. No data were available to infer the age or length at which NFK juvenile salmon outmigrate.

Data suggest that at least some juvenile salmon overwinter in the NFK. Juvenile Chinook salmon have been documented in the NFK as early as April and as late as November (Appendix 15.1B, Tables B.1-2, B.2-2, B.3-7, and B.6-2). During the winter surveys, Chinook salmon were observed only in NFK-B and NFK-C, indicating that these reaches provide overwintering habitat.

Based on field surveys in mainstem habitats, the relative abundance of juvenile Chinook salmon is shown for selected reaches on Figure 15.1-23. In the lowermost NFK reaches (NFK-A, NFK-B, and NFK-C), juvenile Chinook salmon were the second-most abundant salmonid species observed. The greatest abundance of Chinook salmon was in NFK-B, at an estimated 513 fish per 328 feet (100 meters).

Juvenile Chinook salmon were predominantly found in mainstem channel, fast-water habitats (Figure 15.1-24). Few Chinook salmon were found in off-channel habitats (Figure 15.1-25). Densities of juvenile Chinook salmon in the mainstem channel were approximately 5 fish per 1,076 sf (100 m^2), compared to less than 1 fish per 1,076 sf (100 m^2) in side channel and in off-channel habitats (Appendix 15.1B, Figure B.3-11). In the mainstem NFK, densities in riffle and run/glide habitat ranged from approximately 2 to 30 fish per 1,076 sf (100 m^2) compared with approximately 3 fish per 1,076 sf (100 m^2) in pools (Figure 15.1-24). Juvenile Chinook salmon densities in Tributary NFK 1.190 complex ranged from less than 1 to approximately 20 fish per 1,076 sf (100 m^2; Appendix 15.1B, Table B.3-8).

Surveys for adult Chinook salmon in the NFK were conducted annually from 2004 through 2008. During this period, adult Chinook salmon entered the NFK to spawn as early as July 12 and were present as late as August 29 (Figure 15.1-26). The annual spawning run in the NFK was consistently 5 to 6 weeks long, with peak adult counts occurring between July 23 and August 4.

During the study period, the greatest adult Chinook salmon mean index counts were documented in 2004 and 2005 with a declining trend evident from 2006 through 2008 (Figure 15.1-26; Figure 15.1-27). Chinook salmon were the most abundant of the Pacific salmon in the NFK in 2004 and 2005. There was an order of magnitude decline in NFK Chinook salmon mean index counts from 2005 to 2006 (Figure 15.1-27). Total inshore run estimates for the entire Nushagak District (Morstad et al., 2010) and escapement estimates for the Nushagak River (Baker et al., 2009) also showed a decline over time (Table 15.1-15; Figure 15.1-27). At these scales, however, the largest reduction in run size for the Nushagak District and escapement for the Nushagak River was evident in 2007, 1 year later than the observed decline in the NFK mean index counts.

Reach-specific counts allowed for an assessment of the salmon spawner distribution within the NFK watershed. From 2004 through 2008, Chinook salmon spawning was observed in the lower four reaches of the NFK (NFK-A through NFK-D). Analysis of the relative abundance and distribution of spawning salmon among the NFK reaches indicates there was a greater number of spawning Chinook salmon in NFK-A compared to the other NFK reaches (Table 15.1-16; Figure 15.1-28). In 2008, the mean number of spawning adults in NFK-A was 113 fish, while NFK-B and NFK-C supported mean counts of 38 and 47 fish, respectively. In 2008, no spawning Chinook salmon were observed upstream of NFK-C. Adult Chinook salmon are typically associated with mainstem reaches and require sufficient discharge to complete their upstream migration (Appendix 15.1A); therefore, low flows in the upstream portions of the NFK and a general reduction in the amount of suitable spawning gravels may limit spawning for Chinook salmon upstream of NFK-C.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the NFK with respect to the Nushagak District and the greater Bristol Bay fishery. The Nushagak District is one of five fishery districts within Bristol Bay. Chinook salmon within this district, which is comprised of the Wood, Snake, Igushik, and Nushagak rivers, have contributed approximately 81 percent of the total Bristol Bay Chinook salmon catch, based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). The total inshore run estimates (harvest and escapement) provided by ADF&G for Nushagak District Chinook

salmon between 2004 and 2008 ranged from a low of 123,376 fish in 2007 to a high of 244,793 fish in 2005, with a 5-year average of 188,521 (Morstad et al., 2010; Table 15.1-15). During the same time period, Nushagak River Chinook salmon escapement estimates ranged from 53,344 in 2007 to 163,506 in 2005 and had a 5-year average of 106,131 (Baker et al., 2009). In contrast, the NFK Chinook salmon mean index counts (used as an index of escapement) ranged from 157 in 2008 to 1,838 in 2004 and averaged 891 for the 5-year study period (Table 15.1-15; Figure 15.1-27).

Chum Salmon. Chum salmon (*O. keta)* are generally restricted to low-gradient reaches in streams, because their leaping and swimming capabilities are not as strong as other anadromous salmonids (Powers and Orsborn, 1985; Reiser et al., 2006; Appendix 15.1A). A restricted distribution of chum salmon was evident in the NFK. Chum salmon were found from NFK-A through NFK-C (Table 15.1-14). While both juvenile and adult chum salmon have been observed in NFK-C, only adults have been documented in the lower two reaches.

In general, chum salmon fry emergence occurs in late winter and early spring before ice break-up (Appendix 15.1A). Chum salmon are known to seek spawning areas influenced by groundwater upwelling; therefore ice-free conditions would presumably be present at the time of fry emergence. Only 15 juvenile chum salmon were observed in the NFK during the entire study period from 2004 through 2008. These observations were made at three of the winter fish sampling sites in NFK-C in April 2006 (Appendix 15.1B, Table B.3-7). The lack of juvenile chum salmon observations in late spring/early summer, combined with the fact that only young-of-the year (age 0+) have been documented (Figure 15.1-22), indicate juvenile chum salmon only reside in the NFK for a brief period before completing their outmigration. This finding is consistent with the general life history patterns of chum salmon throughout their range, where juveniles are thought to overwinter as subyearlings in estuarine waters (Groot and Margolis, 1998). Chum salmon generally exhibit a much abbreviated river residence time as compared to other Pacific salmon species and are gone from natal rivers within a few weeks after emergence (Appendix 15.1A). In contrast, most juvenile Chinook and coho salmon remain in their natal streams for more than a year before migrating to the sea.

Due to the limited number of juvenile chum salmon observations, little information was obtained regarding juvenile habitat associations in the NFK. However, field survey notes indicate that the three winter fish sampling sites where juvenile chum salmon were observed (NFK06WT-02, NFK06WT-04, and NFK06WT-05; Appendix 15.1B, Figure B.3-22) were a combination of slow- and fast-water habitats, and cobble was the dominant substrate.

Surveys for adult chum salmon in the NFK were conducted annually from 2004 through 2008. Over this 5-year period, chum salmon entered the NFK to spawn as early as July 5 and were present as late as August 15 (Figure 15.1-29). The annual spawning run in the NFK typically lasted for 6 weeks. Peak adult counts occurred between July 12 and July 20. In 2004, chum salmon were observed during only a single NFK survey on July 12, when 435 adults were counted.

Chum salmon are the third most abundant Pacific salmon spawning in the NFK with annual mean index counts between 165 and 532 salmon (Table 15.1-15; Figure 15.1-30). In contrast to Chinook salmon, chum salmon mean index counts in the NFK showed a generally increasing trend over the study period (Figure 15.1-29; Figure 15.1-30). This trend was also observed for UT chum salmon, but was not evident in the SFK or ADF&G's Nushagak District chum salmon total run and Nushagak River escapement estimates (Baker et al., 2009; Morstad et al., 2010). At the larger scale of the Nushagak District, chum

salmon runs increased from 2004 through 2006 and then declined through 2008 (Morstad et al., 2010; Table 15.1-15). Nushagak River chum salmon escapement showed a trend similar to the District total inshore run, although an increase in escapement was observed in 2008 (Baker et al., 2009; Figure 15.1-30).

Reach-specific counts allow for an assessment of the salmon spawner distribution within the watershed. In 2008, chum salmon were observed spawning in the three lowermost NFK reaches (NFK-A through NFK-C; Table 15.1-16; Figure 15.1-28). Analysis of the relative abundance and distribution of spawning salmon among the NFK reaches indicates there is a greater number of spawning chum salmon in NFK-C compared to other reaches. In 2008, the mean number of spawning adults in NFK-C was 326 adults, while NFK-A and NFK-B supported mean spawning counts of 49 and 51, respectively. This spawning distribution pattern is likely due to the distribution of springs and upwelling areas and the hydrologic regime of the NFK. In particular, NFK-C is characterized as a gaining reach, with numerous springs and areas of groundwater upwelling throughout its length (Chapter 7, Section 7.2). Areas of groundwater upwelling likely attract chum salmon spawning in this portion of the NFK watershed. Springs and upwellings are also present in NFK-A and NFK-B, but their distribution is more limited as compared to NFK-C.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the NFK with respect to the Nushagak District and the greater Bristol Bay fishery. Chum salmon within the Nushagak District, which is comprised of the Wood, Snake, Igushik, and Nushagak rivers, contributed approximately 51 percent of the total Bristol Bay catch based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). The total inshore run estimates (commercial catch and escapement) provided by ADF&G for the Nushagak District chum salmon between 2004 and 2008 ranged from a low of 754,053 fish in 2004 to a high of 1,901,238 fish in 2006, with a 5-year average of 1,191,993 (Morstad et al., 2010; Table 15.1-15). During the same time period, Nushagak River chum salmon escapement estimates ranged from 161,483 in 2007 to 661,002 in 2006 and had a 5-year average of 377,724 (Baker et al., 2009). In contrast, the NFK chum salmon mean index counts (used as an index of escapement) ranged from 165 in 2005 to 532 in 2008 and averaged 362 for the 5-year study period (Table 15.1-15; Figure 15.1-30).

Coho Salmon. In contrast to Chinook and chum salmon, coho salmon (*O. kisutch)* were observed in five of the six NFK reaches (NFK-A through NFK-E), including Tributaries NFK 1.190, NFK 1.260, NFK 1.270, and NFK 1.280 (Table 15.1-14; Figure 15.1-20). Adult coho salmon are strong swimmers and generally have shallow body depths compared to the other anadromous salmon in the study area. This shape enables coho salmon to access smaller, shallower, and higher gradient stream channels than other anadromous salmon species.

Coho salmon fry generally emerge between mid-March and May (Appendix 15.1A). Length frequency data indicate four age classes of coho salmon juveniles occur in the NFK: subyearling (0+), yearling (1+), and 2+age and 3+age juveniles. Mean lengths for each age class are shown in Figure 15.1-22. In other systems, the preponderance of juvenile coho salmon overwinter in freshwater and outmigrate as 1+ fish, with some juveniles residing in freshwater for up to 2 years (Appendix 15.1A). In the NFK, it is unclear what proportion of juvenile coho salmon outmigrate as 1+, 2+, or 3+ age fish, especially given the presence of some 3+age fish. Juvenile coho salmon have been observed in the NFK watershed as early as April and as late as November (Appendix 15.1B, Tables B.2-2 and B.3-7). Juvenile coho salmon were

only found in NFK-B and NFK-C during the winter surveys, indicating that these reaches provide overwintering habitat.

The relative abundance of coho salmon juveniles was the highest of all four anadromous salmon species (Figure 15.1-23). In NFK-A through NFK-E, juvenile coho salmon represented the most abundant anadromous salmonid fish. However, they were less abundant than Dolly Varden in NFK-E, and no coho salmon juveniles were found in NFK-F (Table 15.1-14). The greatest relative abundances of coho salmon in the mainstem NFK were observed in NFK-C, where estimates ranged from 210 to 1500 fish per 328 feet (100 m; Figure 15.1-23).

Coho salmon juveniles were found in a variety of habitat types. In NFK-C, where data support density comparisons across mainstem channel, off-channel, and tributary habitat types, coho salmon densities were greatest in side channels (50 fish per 1,076 sf [100 m^2]) and in mainstem channels (25 fish per 1,076 sf [100 m^2]; Appendix 15.1B, Figure B.3-11). Coho salmon were also present in off-channel habitats at a density of 9 fish per 1,076 sf (100 m^2). Within the mainstem NFK, the greatest densities of coho salmon juveniles were found in NFK-C slow water habitats (Figure 15.1-24). The overall highest density (1,154 fish per 1,076 sf [100 m^2]) of juvenile coho salmon was found in backwater habitat that was connected to the mainstem channel within NFK-C. This was followed by more than an order of magnitude lower densities of coho salmon juveniles in pools (74 fish per 1,076 sf [100 m^2]), run/glides (34 fish per 1,076 sf [100 m^2]) and riffles (13 fish per 1,076 sf [100 m^2]). Coho salmon juveniles were also found in riffle habitat in NFK-A and NFK-B at densities of 18 and 35 fish per 1,076 sf (100 m^2), respectively (Figure 15.1-24). Among the off-channel habitat types, alcoves supported the greatest density of coho salmon (234 fish per 1,076 sf [100 m^2]; Figure 15.1-25; Appendix 15.1D). Juvenile coho salmon habitat associations in tributaries were similar to those in the mainstem, with higher densities observed in slow-water habitats (Appendix 15.1B, Table B.3-8).

Surveys for adult coho salmon were conducted annually from 2004 through 2008. Adults were observed entering the NFK as early as August 15 and were present as late as November 6 (Figure 15.1-31). During the 5-year study period, peak adult counts occurred between September 5 and September 28.

In the NFK, coho salmon mean index counts were the lowest of the anadromous salmon species over the study period, with annual mean index counts ranging from 43 to 478 adult salmon (Table 15.1-15; Figure 15.1-32). Similar to chum salmon, they showed a generally increasing trend over the years, with the exception of an order of magnitude decline in 2007. Estimates of coho salmon total run for Nushagak District and escapement to the Nushagak River were not available; however, it is worth noting that catch statistics for the Nushagak District also showed a substantial decline in coho salmon numbers in 2007 (Morstad et al., 2010; Table 15.1-15).

Reach-specific counts allow for an assessment of the salmon spawner distribution within the watershed. During the 2008 study period, coho salmon were observed spawning in five NFK reaches (NFK-A through NFK-E; Table 15.1-16; Figure 15.1-28). As with chum salmon, NFK-C had the greatest number of spawning coho salmon. In 2008, the mean number of spawning adults in NFK-C was 210 adults. NFK-A had approximately half the number of spawning coho salmon (mean spawning count of 106 fish), while NFK-B, NFK-D, and NFK-E had 75 or fewer spawners (Table 15.1-16). This spawning distribution pattern may, in part, be due to the distribution of spawning gravels and the hydrologic regime in the upper portions of NFK-C and NFK-D. In particular, NFK-C is characterized as a gaining stream, with numerous springs and areas of groundwater upwelling throughout its length (Chapter 7, Section 7.2). Upwelling

may potentially serve to attract coho salmon spawning in this portion of the NFK watershed. Additionally, because coho salmon spawn later than the other anadromous salmonids (Appendix 15.1A), access to upstream reaches and tributaries becomes possible once stream flows begin to increase in September and October (Figure 15.1-9).

Mean index counts were used to provide a perspective of the relative size of salmon runs in the NFK with respect to the Nushagak District and the greater Bristol Bay fishery. Coho salmon within the Nushagak District, which is comprised of the Wood, Snake, Igushik, and Nushagak rivers, contributed approximately 31 percent of the total Bristol Bay catch, based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). Nushagak District run estimates and Nushagak River escapement estimates for coho salmon were not available. However, commercial catch for coho salmon in the Nushagak District from 2004 through 2008 ranged from 29,578 fish in 2007 to a high of 73,889 fish in 2008, with a 5-year average of 47,603 (Morstad et al., 2010; Table 15.1-15). Although not directly comparable, the NFK coho salmon mean index counts (used as an index of escapement) ranged from 43 in 2007 to 449 in 2006, and averaged 282 for the 5-year study period (Figure 15.1-32).

Sockeye Salmon. The longitudinal distribution of sockeye salmon (*O. nerka)* in the NFK extended from NFK-A to NFK-D (Table 15.1-14). Over the course of the 5-year study period, adults were observed in all four of these reaches, and juveniles were observed in NFK-A through NFK-C. Sockeye salmon in NFK-D were spawning in Big Wiggly Lake within the Tributary NFK 1.240 drainage, indicating that fry are also present in NFK-D for some period of rearing.

Juvenile sockeye salmon were observed in the NFK in April, July, and August (Appendix 15.1B). Based on length frequency distributions, the only age-class of juvenile sockeye salmon observed in the NFK was young-of-the-year fish (Figure 15.1-22). Sockeye salmon fry emerge in spring and typically move downstream or into lake rearing habitat within 2 to 3 weeks of emergence (Appendix 15.1A).

The relative abundance of juvenile sockeye salmon is shown for selected reaches on Figure 15.1-23. Sockeye salmon were less abundant in the NFK than both Chinook and coho salmon, but were comparable in numbers to chum salmon. This pattern is consistent with the abbreviated riverine residence time of both juvenile sockeye and chum salmon. Juvenile sockeye salmon abundance was similar in NFK-A and NFK-B at 4.0 and 4.5 fish per 328 feet (100 meters), respectively.

Because relatively few sockeye salmon juveniles were observed in the NFK, little information was obtained regarding their habitat associations. The observed fish were located primarily in mainstem habitats and were absent from tributary surveys. Densities were equally low, well below 1 fish per 1,076 sf (100 m^2) in mainstem channel, side channel, and off-channel habitat (Appendix 15.1B, Figure B.3-11), as well as in riffle and pool habitat (Figure 15.1-24). The only observed sockeye salmon juvenile densities greater than 1 fish per 1,076 sf (100 m^2) occurred in alcove off-channel habitats (Figure 15.1-25).

Surveys for adult sockeye salmon were conducted from 2004 through 2008. During the study period, adult sockeye salmon entered the NFK to spawn as early as July 5 and were present as late as September 17 (Figure 15.1-33). Annual peak counts of adult sockeye salmon occurred within a 1-week window from July 27 to August 4. Among the study years, the greatest peak count observed was 2,188 adults in 2007.

NFK sockeye salmon runs were the most stable of the four anadromous salmon runs during the study period. Mean index counts of NFK sockeye salmon ranged from 456 to 648 (Table 15.1-15). Sockeye

salmon were the most abundant of the Pacific salmon spawning in the NFK from 2006 to 2008 (Figure 15.1-34). Sockeye salmon total run estimates provided by ADF&G for the Nushagak District were also relatively stable compared to other species and sockeye salmon runs in other Bristol Bay districts (Morstad et al., 2010). In the Nushagak District, the largest sockeye salmon run from 2004 through 2008 occurred in 2006 (Morstad et al., 2010; Table 15.1-15). In the Nushagak River, sockeye salmon escapement estimates peaked 1 year earlier, in 2005, when escapement was nearly twice that observed in other years during the 5-year study period (Baker et al., 2009). These peaks in total run and escapement estimates were not evident in the NFK sockeye salmon mean index counts.

Reach-specific counts allow for an assessment of the salmon spawner distribution within the watershed. From 2004 through 2008, the observed spawning distribution for sockeye salmon included mainstem habitats in NFK-A, NFK-B, and NFK-C, and Big Wiggly Lake (NFK 1.240.P1) in NFK-D. Analysis of the relative abundance and distribution of spawning salmon among the NFK reaches in 2008 indicates that there was a greater number of spawning sockeye salmon in NFK-A compared to the other NFK reaches (Table 15.1-16; Figure 15.1-28). In 2008, the mean number of spawning adults in NFK-A was 536 fish. NFK-C had the second greatest spawning abundance (225 fish), while NFK-B and NFK-D supported relatively few sockeye salmon spawners.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the NFK with respect to the Nushagak River District and the greater Bristol Bay fishery. Sockeye salmon within the Nushagak District, which is comprised of the Wood, Snake, Igushik, and Nushagak rivers, contribute approximately 20 percent of the total Bristol Bay catch, based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). Total inshore run estimates (commercial catch and escapement) for the Nushagak District sockeye salmon from 2004 through 2008 ranged from a low of 8,248,738 fish in 2004 to a high of 15,738,137 fish in 2006 and had a 5-year average of 11,023,703 fish (Morstad et al., 2010; Table 15.1-15). During the same time period, Nushagak River sockeye salmon escapement estimates ranged from 492,000 in 2004 to 1,049,000 in 2005 and had a 5-year average of 620,000 (Baker et al., 2009). In contrast, the NFK sockeye salmon mean index counts (used as an index of escapement) ranged from 456 in 2006 to 648 in 2007 and averaged 568 for the 5-year study period.

NFK Non-anadromous (Resident) Salmonid Fishes

Non-anadromous salmonid fishes found in the NFK watershed include arctic grayling, Dolly Varden, rainbow trout, and several whitefish species (Table 15.1-17). Although these species are less abundant than anadromous salmonids, they represent an important component of the fish community in this watershed and support local and regional sport and subsistence fisheries. Rainbow trout are particularly important with respect to recreational fisheries. The catch rate for rainbow trout in the Mulchatna drainage averaged 3,993 fish per year from 2000 to 2004 (Dye et al., 2006). Subsistence use of rainbow trout was high and similar to other resident salmonids in 2004 for the towns of Iliamna, Newhalen, and Nondalton (Table 15.1-18; Fall et al., 2006).

The distribution, life history, relative abundance, and habitat associations of each of the four non-anadromous salmonid taxa present in the NFK are discussed below. The mean length of non-anadromous salmonids by age class captured in the NFK is presented on Figure 15.1-35.

Arctic Grayling. The distribution of arctic grayling (*Thymallus arcticus*) in the NFK included NFK-A through NFK-D (Table 15.1-17). Both juvenile and adult arctic grayling have been observed in NFK-A,

NFK-C, and NFK-D; only adults were observed in NFK-B. In comparison to the anadromous salmonids, relatively little data are available to describe stream-specific life history characteristics of arctic grayling in the NFK. Elsewhere in their range, adults overwinter in lakes or mainstem channels and migrate to upstream tributaries to spawn in May and June (see Appendix 15.1A). Following spawning, adults may return to lakes or mainstem channels or remain in upstream tributaries for a summer feeding season. In the NFK, adults have been observed from May through October, with no discernable pattern in the timing of the reaches they inhabit. Likewise, juvenile grayling have been seen from May through October in multiple reaches.

The relative abundance of arctic grayling in NFK-C is shown on Figure 15.1-23. Relatively few arctic grayling were observed in NFK-A and NFK-B (Appendix 15.1B, Tables B.1-2 and B.2-2). Abundance increased in NFK-C, where estimates ranged from 3 to 125 fish per 328 feet (100 meters). Overall, arctic grayling were less abundant than Chinook and coho salmon, similar in numbers to sockeye salmon and Dolly Varden, and more abundant than chum salmon and rainbow trout (Figure 15.1-23).

NFK-C was the only reach in which the density of arctic grayling could be compared across multiple channel and habitat types. Arctic grayling were observed in low numbers (less than 1 fish per 1,076 sf [100 m^2]) in mainstem channel habitats and absent in off-channel and side channel habitats surveyed in NFK-C (Appendix 15.1B, Figure B.3-11). Grayling were present in fast and slow water habitats in the mainstem NFK (Figure 15.1-24) and in the Tributary 1.190 complex (Appendix 15.1B, Figure B.3-9b). Arctic grayling were found primarily in mainstem pool habitats at approximately 5 fish per 1,076 sf (100 m^2). Densities in other mainstem and tributary habitats were less than 1 fish per 1,076 sf (100 m^2).

Dolly Varden. Dolly Varden (*Salvelinus malma*) were ubiquitous within all six reaches of the NFK (Table 15.1-17) and were found in both mainstem and tributary habitats (Appendix 15.1B). Juvenile and adult life history stages have been observed in all six reaches.

Both anadromous and non-anadromous populations of Dolly Varden are thought to exist within the Bristol Bay region (see Appendix 15.1A). Dolly Varden populations in the NFK are thought to be non-anadromous, because no evidence of anadromy was found during the 5 years of study. However, relatively little information has been collected regarding specific life history pattern(s) in the NFK. These patterns can be complex, with variations in spawning frequency, migration timing, and selection of overwintering sites. Adults have been observed in July, August, and September, while juveniles have been seen in April, July through September, and November (Appendix 15.1B, Tables B.1-2, B.2-2, B.3-7, B.4-2, B.5-2, and B.6-2).

The relative abundance of juvenile and adult Dolly Varden is shown for reaches with available data on Figure 15.1-23. Like arctic grayling, relatively few Dolly Varden were observed in NFK-A and NFK-B (Appendix 15.1B, Tables B.1-2 and B.2-2). The estimated abundance of Dolly Varden in NFK-C mainstem habitats ranged from 15 to 37 fish per 328 feet (100 meters; Figure 15.1-23). Within the Tributary 1.190 complex, the range of abundance estimates was much greater, from less than 1 to greater than 700 fish per 328 feet (100 meters; Appendix 15.1B, Table B.3-8b). Overall, Dolly Varden were less abundant than Chinook and coho salmon, similar in numbers to sockeye salmon and arctic grayling, and more abundant than chum salmon and rainbow trout (Figure 15.1-23).

The NFK-C was the only reach in which the density of Dolly Varden could be compared across multiple habitat types (Figure 15.1-24). Dolly Varden were present in mainstem channel, off-channel, and side

channel habitats (Appendix 15.1B, Figure B.3-11). Mainstem NFK densities were generally less than 3 fish per 1,076 sf (100 m^2) in all habitats (Figure 15.1-24). The density in Tributary 1.190 and in smaller tributaries was more variable and ranged from 5 fish per 1,076 sf (100 m^2) in riffle and cascade habitat to over 105 fish per 1,076 sf (100 m^2) in backwater habitat (Appendix 15.1B, Figure B.3-9b). Dolly Varden densities in off-channel habitats ranged from less than 1 fish per 1,076 sf (100 m^2) in beaver ponds to approximately 16 fish per 1,076 sf (100 m^2) in side channel habitat (Figure 15.1-36).

Rainbow Trout. Rainbow trout (*O. mykiss)* were only found in NFK-A and NFK-C (Table 15.1-17). In each of these reaches, observations included both adult and juvenile rainbow trout.

Only non-anadromous populations of rainbow trout are thought to occur in the Bristol Bay watersheds (see Appendix 15.1A). To date, there is no evidence of anadromy in the NFK rainbow trout populations. Little information was available or has been collected to describe stream-specific life history characteristics of rainbow trout in the NFK. Whereas most of the salmonid species present in the study area spawn in the summer or fall, rainbow trout are spring spawners. Small numbers of adult rainbow trout have been documented in the NFK in July and August, while juveniles have been observed in July, August, and September (Appendix 15.1B). Given the relatively small number of observations, no reach-specific utilization or migration patterns were discernable.

Overall, few collections and observations of rainbow trout were made during the NFK fish surveys (Appendix 15.1B). The relative abundance of rainbow trout in the mainstem NFK was less than 1 fish per 328 feet (100 meters; Figure 15.1-23). Relative abundance in Tributary NFK 1.190 was slightly greater, ranging from less than 1 to approximately 3 fish per 328 feet (100 meters; Appendix 15.1B, Figure B.3-8b). Rainbow trout occupied both fast- and slow-water habitats in the NFK, including backwater, cascade, pool, riffle, and run/glide, although densities in these habitat types were approximately or less than 1 fish per 1,076 sf (100 m^2; Appendix 15.1B, Figure B.3-9).

Whitefish. Representatives of the whitefish species group (Coregoninae) that were found in the NFK watershed included round whitefish (*Prosopium cylindraceum*), humpback whitefish (*Coregonus pidschian*), and the least cisco (*C. sardinella*). Fish belonging to this species group were documented from NFK-A through NFK-D (Table 15.1-17). In many cases, these fish were observed during snorkel surveys and could not be identified to species. Observations in the NFK-C during the study period identified round whitefish, while Buell (1994) documented both humpback whitefish and least cisco in the NFK. Whitefish observations in the NFK during the baseline study period were limited to the adult life stage. Adults were observed in the NFK as late as September (Appendix 15.1B). Although adult whitefish were found within the mainstem channel of NFK C, abundance estimates were low, ranging from less than 1 to approximately 18 fish per 328 feet (100 meters; Figure 15.1-23). Whitefish were not observed or captured in the tributaries. Whitefish spawning is thought to occur during the fall (Appendix 15.1A);however, no juvenile whitefish were observed during the study period.

NFK Non-Salmonid Fishes

Non-salmonid fishes found in the NFK watershed include northern pike, sculpin, and stickleback (Table 15.1-19). Of these three species, only northern pike are valued as a subsistence and sport fish to local communities. Information regarding the distribution, relative abundance, and habitat associations of these three non-salmonid species groups in the NFK is provided below.

Northern Pike. Juvenile and adult northern pike were documented in reaches NFK-C and NFK-D (Table 15.1-19). Adult pike were observed from June through October, while juveniles were recorded between July and November (Appendix 15.1B, Tables B.3-7 and B.4-2). These observations were made primarily in lakes or in outlet streams of lakes, with the majority of the observations occurring in Big Wiggly and Black lakes. During the 2008 mainstem index surveys, a single juvenile northern pike was observed in riffle habitat within NFK-D (Appendix 15.1B, Table B.4-4 and Figure B.4-14b).

Sculpin. Sculpin (*Cottus* sp.) have been documented in all reaches of the NFK, making it among the most widely distributed species in this watershed (Table 15.1-19). Although sculpin were not identified to species, both slimy sculpin *(Cottus cognatus*) and coast range sculpin (*Cottus aleuticus*) are known to inhabit the Bristol Bay basin (Appendix15.1A), and slimy sculpin have been previously documented in the NFK by Buell (1994) and ADF&G (2006b). During the 2004 through 2008 environmental baseline studies, both juvenile and adult sculpin were documented throughout the NFK, with the exception of NFK-E — where only juvenile and indeterminate life stages were observed.

The relative abundance of sculpin was generally low where they were documented. The exception was in NFK-C, where sculpin abundance ranged from 29 to 58 fish per 328 feet (100 meters) in the NFK mainstem (Figure 15.1-23) and from approximately 2 to 240 fish per 328 feet (100 meters) in NFK-C tributaries (Appendix 15.1B, Figure B.3-8b). Among the various mainstem channel habitat types, sculpin were most dense in backwater/sloughs (31 fish per 1,076 sf [100 m^2]) in the NFK-C mainstem (Figure 15.1-24) and in riffle and run/glide habitats within the Tributary 1.190 complex (approximately 30 to 45 fish per 1,076 sf [100 m^2]; Appendix 15.1B, Figure B.3-9b). In off-channel habitats, sculpin were found mostly in flowing habitat types, such as percolation channels and side channels, at densities less than 4 fish per 1,076 sf (100 m^2; Figure 15.1-36).

Stickleback. In the NFK, stickleback (Gasterosteidae) have been documented in NFK-A through NFK-D (Table 15.1-19). Consistent with the findings of Buell (1994), current observations included both juvenile and adult ninespine stickleback *(Pungitius pungitius)* and threespine stickleback *(Gasterosteus aculeatus)*.

Stickleback were observed in the NFK mainstem, in Tributaries 1.220, 1.240, and 1.270, and in off-channel habitats. Stickleback were primarily located in beaver ponds and associated outlet channels at densities of 1 and 25 fish per 1,076 sf (100 m^2), respectively (Figure 15.1-36) and were often the most abundant species in slackwater. Few, if any, stickleback were present in other off-channel habitats. The estimated stickleback density in glide habitat at one mainstem index site in 2008 was 0.45 fish per 1,076 sf (100 m^2; Appendix 15.1B, Table B.4-14a).

NFK Watershed Synthesis

Anadromous salmon spawn throughout the NFK. However, most of the spawning occurs in the lower and middle mainstem river reaches (NFK-A, NFK-B, and NFK-C). An assessment of individual anadromous species spawning distributions indicates that Chinook salmon use the large river reaches low in the drainage watershed. The greatest abundance of Chinook, as well as sockeye salmon, spawners during the baseline period was observed in NFK-A. Conversely, coho salmon spawning was ubiquitous throughout the NFK mainstem and tributary reaches. Nevertheless, the greatest abundance of coho and chum salmon, as well as chum salmon spawners, was found in NFK-C. The instream-flow model predictions help explain these patterns based on relationships between substrate sizes, water velocities, and species preferences for these criteria. In NFK-A, the model predicts the highest amounts of available Chinook

salmon spawning habitat, while the highest amounts of available coho and chum salmon spawning habitat were predicted in NFK-C. No similarity of pattern was evident for sockeye salmon. When considering the within-reach spawning distributions of sockeye salmon, and to a large extent chum salmon, a direct association between spawning area and areas identified as gaining reaches due to inflow from groundwater, seeps, or springs was evident.

The NFK thermal regime may also influence fish spawning distributions. The NFK exhibits a sharp temperature decline near the top of NFK-C where Tributary NFK 1.190 enters the mainstem channel. Flows from Tributary NFK 1.190 cool the river downstream as indicated by both instantaneous and monthly temperatures (Appendix 15.1E). NFK reaches above NFK 1.190 are warmer, and instantaneous temperatures have been documented that both exceed optimal temperatures for spawning and incubation and are higher than maximum temperatures recorded for other regional rivers. The arrival of coho salmon to the NFK coincides with onset of fall rains that help ensure adequate flows and temperatures for spawning in upper reaches. These flows and temperatures are not available to other species entering the river basin earlier in the season.

Although little spawning was observed in NFK-D over the study period, this reach contains habitat that supports a distinct life history strategy for sockeye salmon. Tributary NFK 1.240 drains into NFK-D at RM 27.92 (RK 44.93). Big Wiggly Lake in the NFK 1.240 drainage supports a population of lake-spawning sockeye salmon. Approximately 514 adult sockeye salmon were counted in these lakes in 2008. Limited sampling around the lake perimeter was unable to determine if juvenile rearing is occurring in these lakes as well, but rearing is assumed to occur in NFK-D and reaches downstream.

Based on mean index counts, the NFK supported the largest run of Chinook and chum salmon among the three watersheds in the study area. The abundance of Chinook and chum salmon runs in the SFK follow closely behind NFK. Coho salmon mean index counts were similar in the NFK and SFK and were substantially less in the NFK than in the UT (see Sections 15.1.6.2 and 15.1.6.3). The sockeye salmon run in the NFK was consistent year to year, yet it was the smallest run among the three watersheds.

The distributions of river-rearing, juvenile Pacific salmon follow similar patterns as the spawning distributions. Juvenile Chinook salmon were prominent in mainstem channel, fast-water habitats that dominated the lower three reaches of the NFK. Juvenile coho salmon, on the other hand, were widely dispersed throughout the mainstem NFK and in several tributaries and occupied numerous habitats. Off-channel habitat appeared particularly important to coho salmon rearing, because they were observed at their highest densities in off-channel backwater and alcove habitats. This wide distribution and broad habitat use for juvenile coho salmon is consistent with the fact that they were the most abundant juvenile fish species documented in the NFK.

Patterns evident for juvenile sockeye salmon distribution were also noteworthy. Sockeye salmon typically outmigrate from the river reaches in their first spring after emergence as subyearling fish (Appendix 15.1A). Thus, the observations of juvenile sockeye salmon in the middle NFK in April was not surprising. However, juvenile sockeye salmon also were documented in NFK-A, NFK-B, and NFK-C during summer sampling, indicating that some sockeye are rearing for at least several months within the NFK.

At least nine non-anadromous salmonid and non-salmonid fishes were present in the NFK during the study period. In general, these stream-dwelling fishes were distributed in low numbers throughout the lower reaches (NFK-A, NFK-B, and NFK-C). Arctic grayling, northern pike, and stickleback species also

were found in NFK-D. Dolly Varden and the sculpin species were the most widespread of non-anadromous fishes and were documented in all reaches as well as several tributaries. Relative abundance of these fishes was generally low, with the exception of Dolly Varden and sculpin in NFK-C. Although juvenile Chinook and coho salmon dominated the mainstem habitat in NFK-A, NFK-B, and NFK-C, Dolly Varden exhibited the highest relative abundance among all fishes within NFK-C tributaries.

Within the NFK, NFK-C and NFK-D had the most diverse species assemblages, and NFK-C and Tributary NFK 1.190 supported the highest relative abundance of the fishes documented over the study period. The abundance and diversity of fish in NFK-C did not appear to be driven by habitat availability. As predicted by the instream-flow model, NFK-B should provide much more available habitat for all juvenile salmonids except rainbow trout, and the highest estimates of available spawning habitat for four out of seven salmonids was in NFK-A. The habitat quality in NFK-C may be a factor influencing the richness of fish species. NFK-C gained inflow from Tributary 1.190, as well numerous seeps and springs located along the mainstem channel margin (Chapter 9, Section 9.1). Tributary 1.190 was also largely influenced by seeps and springs and contributed cooler water to NFK-C, providing an enhanced thermal regime to habitats downstream compared to those upstream in NFK-D, NFK-E, and NFK-F. Of the summer maxima temperature recorded during the study period in NFK-D, 78 percent exceeded rearing standards for salmonid fishes. The recorded high temperatures in the NFK are several degrees higher than those reported for other streams in the region, except for the SFK.

Intermittent stream flows were generally not a concern along mainstem channels in the NFK. However, reduced flows in some of the tributaries could potentially limit fish production on a local level. For example, Tributary NFK 1.190.10 routinely exhibited late summer intermittent flow conditions, immediately upstream of its confluence with Tributary NFK 1.190. The total length of dry stream channel in this tributary was slightly more than 2 miles (3.2 km).

The data collected during the study period reveal the preponderance of fish spawning and rearing in the NFK occurred in areas with a surface water expression of groundwater. These areas of detectable groundwater influence were widespread throughout the lower three reaches, with areas of higher groundwater concentration noted in the upper portion of NFK-B, NFK-C, and Tributary 1.190 (Chapter 7, Section 7.2). In areas where groundwater influx was not prevalent, fish diversity and abundance were reduced.

15.1.6.2 South Fork Koktuli Watershed

SFK Watershed Overview

The SFK is another relatively small drainage of the Nushagak-Mulchatna river system. The Nushagak basin is one of eight river basins draining Southwest Alaska into Bristol Bay (Figure 15.1-5). The headwaters of the SFK are situated in the Pebble Deposit area (Figure 15.1-37). The SFK drainage area comprises 107 mi^2 (277 km^2), which represents about 0.8 percent of the Nushagak-Mulchatna system and 0.3 percent of the entire Bristol Bay drainage basin (Table 15.1-2). The SFK includes an overall mainstem stream length of approximately 40 miles (64 km).

The SFK originates on the east flank of Kaskanak Mountain northwest of Frying Pan Lake (Figure 15.1-37). The SFK flows south then west before joining the NFK to form the KR. The highest elevation in the SFK drainage is Kaskanak Mountain (elevation 2,759 feet [841 meters]). The lowest elevation in the

watershed is at the confluence with the NFK at 580 feet (177 meters; Chapter 4). The watershed is bounded by a series of low, isolated mountain blocks, with Kaskanak Mountain to the north and west, Koktuli Mountain to the east, and Sharp Mountain to the south. Like the NFK, the northern surface water drainage divide is not well defined.

A general map of fish resources study site locations in the SFK is shown on Figure 15.1-38. This map depicts 1,887 individual study site locations sampled between 2004 and 2008.

SFK Aquatic Habitat

This section describes the physical, chemical, and biological components of aquatic habitat in the SFK. These habitat components are discussed in distinct sections to facilitate comparison among watersheds.

SFK Physical Habitat Conditions

The mainstem SFK has been divided into five stream reaches with distinct hydrology, geology, and channel characteristics (Figure 15.1-37; Table 15.1-20). The five reach designations (SFK-A through SFK-E) progress from downstream to upstream along the length of the mainstem SFK, and SFK-E includes an impounded segment near the headwaters formed by Frying Pan Lake. As discussed in Section 15.1.1, tributaries were assigned to the mainstem reach into which they flowed, and off-channel habitats were assigned to a mainstem reach based on their proximity to the mainstem channel. Photographs depicting representative channel and surrounding habitat characteristics of each reach are provided in Photos 15.1-17 through 15.1-21.

Channel Morphology. The SFK is primarily a single-thread, gravel-bedded channel with a geomorphic tendency toward a meandering planform. Channel gradients in the SFK were the lowest of the three watersheds and ranged from 0.03 to 0.60 percent, while averaging 0.20 percent at the FG study sites. Large woody debris was scarce throughout the SFK due to a general lack of forest vegetation within the riparian zone. Large boulders deposited by retreating glaciers were sporadically located within the SFK channel and provide instream cover, feeding station, and velocity shelter habitat for fish.

Like the NFK, the primary sources of sediment in the channel were from undercut banks and lateral erosion that occurs during high flows and ice break-up processes. Valley bottom deposits in the two lowermost reaches (SFK-A and SFK-B—downstream of Tributary SFK 1.190) consisted of reworked glacial outwash material, including abandoned stream terraces and recent alluvial deposits (Appendix 15.1F). These reaches were flanked by glacial moraine and drift deposits.

High flows have typically overflowed the banks, and large channels were bordered by floodplains and former stream terraces. Associated riparian zones, wetland complexes, and off-channel habitat extended well beyond the stream banks. Sediment sources consisted primarily of fluvial transport from upstream reaches and bank erosion. SFK-A and SFK-B exhibited an alluvial channel morphology that appears to reflect adjustment to the post-glacial flow regime (Appendix 15.1F). SFK-C, located upstream of Tributary SFK 1.190, flowed through glacial lacustrine (related to a lake environment) deposits and was relatively low gradient compared to the rest of the mainstem, with channel slopes on the order of 0.03 to 0.07 percent.

SFK-D flowed through primarily alluvial deposits with a high percentage of sand-sized materials. Portions of SFK-D contained stratified layers of gravel and lake deposits in the banks. The downstream end of the reach represents the lower limit to beaver dam construction across the mainstem channel. The drainage area at this point (approximately 18 mi^2 [47 km^2]) was nearly twice the corresponding area limit of mainstem beaver activity in the other two study rivers (10 to 11 mi^2 [26 to 28 km^2]; Appendix 15.1F). This result may reflect the attenuating influence of Frying Pan Lake on high flows in the SFK.

Upstream of Frying Pan Lake, SFK-E flowed across a former glacial lakebed, where fine sediments and organic materials were common and soils less well-drained. As a result, glacial lake deposits were prevalent in SFK-E upstream of Frying Pan Lake. The reach was represented by a palustrine (related to wetlands) channel type that typically contains more fine sediments than channel reaches elsewhere in the SFK watershed. Tributary channels flowing from the isolated mountain blocks into the middle of SFK-E were high and moderate gradient alluvial fan channels.

Hydrology. The surface water hydrology of the mine study area is described in detail as part of the Pebble Project EBD (Chapter 7, Section 7.2). The surface water hydrologic regime of the SFK is strongly influenced by climate, geology, and groundwater, with stream flows driven by runoff from spring snowmelt and summer/fall rains.

Seasonal flows in the SFK generally have two peaks (Figure 15.1-39), similar to other streams in Southwestern Alaska, and similar to the adjoining watersheds in the mine study area. The first peak occurs during the spring snowmelt season (with the majority of the snowmelt runoff typically occurring in May), while the second peak occurs during the fall rainy season (late August to November). These peaks are separated by two low flow seasons: a summer low flow (with minimum flows typically occurring in August), and a winter low flow (with minimum flows typically occurring in late March to late April).

The mean annual flow in the SFK was 191 cfs (5.4 m^3/s) during water years 2005 through 2008 at Hydrology Gage SK100B (USGS Gage No. 15302200). This discharge was equivalent to a mean annual unit runoff of 37.4 inches (95.0 centimeters) from the 69 mi^2 (180 km^2) watershed area at the gage. The lowermost gage in the SFK watershed (SK 100A), located prior to the confluence with the NFK, recorded a mean annual discharge of 269 cfs (7.6 m^3/s) between 2005 and 2008.

Runoff was flashy in steep tributaries that drain the isolated mountain blocks where groundwater storage is limited. In contrast, the mainstem SFK exhibited a pronounced groundwater influence. From the outlet of Frying Pan Lake downstream through SFK-C, the river flows generally decreased in a downstream direction as water infiltrated into permeable glacial outwash sediments. Portions of this section of the river often dry up in the late summer and have exhibited subsurface flows during the winter base flow period. For example, in March 2005, flows were 8.3 cfs (0.2 m^3/s) at the SK100F gage (RK 54.7) and 0 cfs (0 m^3/s) at the SK100C gage (RK 35.8) despite the contributing drainage area more than tripling between the two gage sites, from 11.9 to 37.5 mi^2 (31 to97 km^2; Chapter 7, Section 7.2). Groundwater flowed down valley to the southwest, but also to the southeast along a series of former glacial drainage-ways. Approximately 22 cfs (0.6 m^3/s) of groundwater flowed out of the SFK watershed and emerged in a tributary to the UT (UT 1.190).

Stream flow in the SFK was augmented by groundwater in the lower portion of SFK-B and SFK-A, where the river flowed across the western end of the terminal moraine and entered the relatively narrow valley between Kaskanak Mountain and Sharp Mountain. Springs, seeps, and upwelling groundwater

were common in the upstream end of this section of river. Documented base flow increases in this section were from 0.3 to almost 27 cfs (0.01 to 0.8 m^3/s) over a distance of 2.9 miles (4.6 km), with less than a 10 percent increase in contributing surface area (Chapter 7, Section 7.2). Groundwater contributions influenced conditions in this portion of the river year round. Ice-free (open water) conditions reflected the warming influence of groundwater observed throughout the winter. Like the NFK, the hydrologic regime of the SFK has a substantial influence on the functionality and usability of fish habitat and, in turn, the distribution and abundance of fish that use the watershed.

Water Temperature. Water temperatures in the SFK watershed begin to seasonally warm in May and June and generally peak in July and August. Temperatures cool during September and October and remain near freezing from November through April. A series of temperature plots during calendar year 2007 at select SFK gages is shown on Figure 15.1-40 to demonstrate the general thermal regime across the watershed. More detailed temperature data, as well as a description of the SNTEMP flow-sensitive surface water temperature models that were developed and calibrated using these baseline data, are provided in Appendix 15.1E.

The longitudinal thermal regime of the SFK is characteristic of a surface water system influenced by groundwater inflow (Figure 15.1-41). In most streams, water temperatures would be expected to increase in the downstream direction because air temperatures generally increase with decreasing elevations. However, after a bit of warming from Frying Pan Lake, the SFK exhibited the opposite trend—with warmer summer (June, July and August) temperatures found in SFK-C and SFK-D just below Frying Pan Lake and relatively cool temperatures in the downstream reaches (SFK-A and SFK-B). In 2007, mean daily summer water temperatures declined approximately 41ºF (5ºC) in the mainstem between SFK-C and SFK-B. Water temperatures, combined with flow records, indicated that the mainstem received groundwater inflow in SFK-B that was relatively cool in the summer, and relatively warm in the winter. The downstream reaches (including SFK-B) remain generally ice-free, the open water conditions reflecting the warming influence of groundwater observed throughout the winter (Chapter 7, Section 7.2, Figure 7.2-5).

While water temperatures remained at or near freezing during the winter season throughout most of the SFK, there was greater variability in water temperatures during the summer (Appendix 15.1E). The daily temperature range during the summer months for all monitoring gages and years for the SFK watershed is provided in Table 15.1-21. The instantaneous minimum and maximum daily temperatures ranged from a low of 35ºF (1.1ºC) at monitoring site SK119A in Tributary SFK 1.190, which discharges into SFK-B, in 2006 to a high of 75.9ºF (24.4ºC) at monitoring gage SK100F in 2004.

Instantaneous summertime maximum temperatures exceeded the ADEC maximum water temperature standard for aquatic life of 68ºF (20ºC; ADEC, 2009) at SK100F in 2004, 2005, and 2007, at station SK100G in 2005, and at SK100C in 2007 (Table 15.1-21), representing 17 percent of the total maximum summer temperature recordings. Summer temperature data indicate the ADEC maximum water temperature standard for spawning and egg and fry incubation of 55ºF (13ºC; ADEC, 2009) was exceeded for 93 percent of the records, and the ADEC maximum water temperature standard for migration routes and rearing areas of 59ºF (15ºC; ADEC, 2009) was exceeded for 76 percent of the summer records during the baseline period.

The thermal regime of the SFK likely has had an influence on the behavior, metabolism, and growth of fish and their use of specific habitats. In the study area where freezing and low water temperatures are a

concern, fish would be attracted to groundwater-fed channels during the winter and early spring, because these sites represent areas of stable flows and relatively warm water temperatures (Leman, 1993; Ebersole et al., 2003). Groundwater inflow offers temperature moderation in both the mainstem and tributary reaches in winter such that a portion of these areas remains ice-free (Chapter 7, Section 7.2, Figure 7.2-5). These areas may provide overwintering habitat that is often limited in northern streams, and as such, enhance the survival of incubating embryos compared to frozen stream reaches. In contrast, between the outlet of Frying Pan Lake downstream through SFK-C, the river was either losing surface water flow to subsurface layers or receiving warm water runoff from ponds and lakes. As a result, the shallow cross sections have allowed the remaining surface waters to heat more rapidly than in stable and gaining flow sections of the river. Although summer season stream temperatures in SFK were mostly cool, summer rearing conditions may be limited in portions of the mainstem from Frying Pan Lake downstream and including the upper portion of SFK-B due to these warming factors.

Throughout the majority of the year, the water temperature regime of the SFK is cold, severely restricting rearing conditions. Because fish are cold-blooded species (cannot regulate their body temperature) all metabolism, activity, swimming speed, and behavior are directly a result of ambient water temperature conditions. Cold water restricts active focal-point feeding behavior to a brief period (late May through mid-September) when water temperatures exceed 46ºF (8ºC; Campbell and Neuner, 1985). As a result, productivity of the fish populations can be thermally-limited compared to watersheds where the active feeding period is longer. Notably, in this cold water river, warmer water temperatures in the summer months also may be limiting to fish health and productivity. Given the open riparian nature of most of the streams in the SFK watershed, water temperatures warm quickly during the summer months and have naturally exceeded state thermal criteria for spawning, incubation, migration, and rearing habitat at a number of monitoring stations, especially upstream of SFK-B (Table 15.1-21).

Mainstem Channel Habitat. The baseline frequencies of mesohabitat types (e.g., pool, riffle, run/glide, etc.) are itemized at the reach level in Appendix 15.1B and summarized at the watershed scale level for the mainstem SFK on Figure 15.1-42. Riffle and run/glide habitats were the predominant habitat types in SFK-A through SFK-D. Pool habitat and beaver ponds were relatively sparse; there was less than 5 percent pool habitat in reaches SFK-A through SFK-D, and SFK-D was the only reach with a substantial amount of beaver-created habitat (18 percent; Figure 15.1-42). The frequency of USFS channel types along selected reaches in the SFK and the results of Tier 3 field surveys are shown on Figures 15.1-43 and 15.1-44, respectively. A list and descriptions of USFS channel type codes are provided in Table 15.1-5. In general, all of the habitat studies indicate that the SFK was comprised mostly of riffle and run/glide habitats with relatively few pools. Although widespread in off-channel habitats, beaver ponds were not prevalent in the mainstem reaches downstream of SFK-D accounting, in some part, for a lack of pools in these reaches. As noted above, large woody debris was generally absent within the SFK due to a lack of forest vegetation in the study area. As a result, instream cover for fish was largely provided by undercut banks and overhanging vegetation, along with scattered boulders and cobble materials that form velocity breaks and create feeding stations.

Overall, the prevalence of riffle and run/glide habitats within the SFK suggests the presence of substantial quantities of spawning habitat. This concept was confirmed as part of adult salmon surveys and redd measurements (see Fish Resources section below). However, given the lack of pools and slackwater habitat features in the mainstem river, both summer and winter rearing habitats might be more prevalent in off-channel waterbodies.

Pacific salmon require cold, clear, and well oxygenated water with gravel- to cobble-sized substrates for spawning. The quality of spawning gravels was good, based on grain size analysis of bulk substrate samples collected from three locations in the SFK. Although the levels of fine sediments in samples collected from the SFK were higher than levels found in samples from the NFK and UT, the concentrations of size fractions that have been related to embryo survival (size fraction less than 0.03 inches or 0.84 millimeters) and fry emergence (less than 0.25 inches or 6.4 millimeters) were all below levels considered harmful (less than 12 percent and 20 percent, respectively; after Shirazi et al., 1981; Lotspeich and Everest, 1981; Chapman and McLeod, 1987; Reiser and White, 1988; Kondolf, 2000). See Appendix 15.1F for detailed results of the spawning gravel analysis.

Off-channel Habitat. Like the NFK, the SFK system contained a substantial amount of off-channel habitat comprised of side channels, alcoves, overflow channels, beaver ponds, and isolated ponds (Figure 15.1-45). The SFK off-channel habitat study site contained an estimated 46 acres of off-channel habitat (Table 15.1-22). The most frequently encountered off-channel habitat type was beaver ponds (91 percent). These features typically included a combination of ponded areas and outlet channels that create both pool and slow moving run/glide type habitats. With the exception of isolated ponds that are only connected to the mainstem channel during overbank flows, off-channel habitats can potentially be used by a diverse assemblage of fish species and life stages at a range of mainstem channel flows.

Survey results indicated that many of the off-channel habitat sites were hydrologically connected to the mainstem channel via surface inflow at less than bankfull flows (approximately 620 cfs [18 m^3/s]; Appendix 15.1D). A subsample of 11 off-channel habitat sites showed the engagement of sites varied broadly within and between off-channel habitat types (Table 15.1-23). See Appendix 15.1D for more information regarding the off-channel flow study.

SFK Chemical Habitat Conditions

A comparison of various water quality parameters reported in the mine study area and those reported for other water quality studies in the region is provided in Table 15.1-8. These parameters include water temperature, DO, specific conductance, pH, turbidity, alkalinity, and hardness. Similar to the NFK, the water quality within the SFK watershed was generally good and supported a range of salmonid and non-salmonid fishes. Overall, the SFK water quality parameter values were similar to those for other watersheds in the region (Table 15.1-8). The notable exceptions include: a maximum water temperature of 74.3ºF (23.5ºC), which is greater than those reported for other watersheds; a DO minimum of 2.2 mg/L, which is the lowest DO concentration reported for the watersheds shown in Table 15.1-8; and a broader range of reported values for pH, alkalinity, and water hardness. Some concentrations were found to vary as a factor of flow conditions, location within the watershed, or season (Chapter 9, Section 9.1).

In addition to the water quality parameters included in Table 15.1-8, concentrations of trace elements, cyanides, and nutrients were determined as part of the surface water quality studies in the mine study area (Chapter 9, Section 9.1). As in the NFK, natural exceedences of estimated freshwater aquatic life criteria were observed in the SFK for aluminum (total), cadmium (total and dissolved), copper (total and dissolved), iron (total), lead (total and dissolved), zinc (total), and weak acid dissociable (WAD) cyanide. In addition, exceedences were observed for dissolved zinc and total mercury. The percent of samples exceeding the criteria for total aluminum (12 percent) and total and dissolved copper (approximately 42 and 34 percent, respectively) was greater in the SFK than in the NFK. All total aluminum samples from one mainstem location (SK100E) and from two tributary locations (SK116A and SK117A) had

concentrations naturally above criteria. Nearly all total copper samples from three locations (SK100G, SK100H, and SK100I) had concentrations naturally above criteria. These three sampling sites are located upstream of Frying Pan and are within or in the vicinity of the deposit location. Copper exceedences decreased in frequency and magnitude as the distance of the sampling location from the headwater areas increased. Lead exceeded criteria in approximately 6 percent of the dissolved samples and approximately 15.5 percent of the total samples. Similar to the NFK, no pattern was evident for lead exceedences, which suggests that naturally occurring elevated lead concentrations may be distributed throughout the SFK. Mean nutrient concentrations are generally low.

SFK Aquatic Macroinvertebrates

Like the NFK, studies of both the periphyton and aquatic invertebrate communities have been conducted in the SFK and detailed results are described in Section 15.2. Because of the importance of macroinvertebrates as both food for fish and as indicators of stream health, annual results of the macroinvertebrate studies in the SFK are summarized for June sampling efforts below.

The macroinvertebrate taxa richness of three sample sites (SK-100A, SK-100B, and SK-100D) is shown on Figure 15.1-46. As in the NFK, taxa richness was determined for June sampling efforts in 2004, 2005, and 2007 using two different collection methods: the ASCI kick net and Surber methods. Taxa richness ranged from a low of 15taxa at SK-100D in 2007 (ASCI method) to a high of 28 taxa at SK-100A in 2007 (ASCI method; Figure 15.1-46). The results across the three years of sampling for SK-100B suggest slightly increased mean taxa richness in 2007. In 2007, the mean taxa richness was lower in the upstream area of the watershed (SK-100D) compared to the stations (SK-100A and SK-100B) in lower elevation reaches.

Like the NFK, the macroinvertebrate communities in the SFK are largely composed of midge larvae (Family Chironomidae) and EPT taxa. The contribution of chironomids at the three sample sites ranged from 38 percent at SK-100D in 2007 (Surber method) to 91 percent at SK-100B in 2005 (Surber method; Figure 15.1-46). For EPT taxa, percentages ranged approximately 2 percent at SK-100B in 2007 (Surber method) to 40 percent at SK-100D in 2007 (Surber method). The macroinvertebrate communities at SK-100A and SK-100B were dominated by chironomids,. At SK-100D, EPT taxa and chironomids were present in more equal proportions, particularly for the Surber method.

SFK Habitat/Flow Relationships

This section presents the results of instream flow habitat modeling and time series analyses computed for various salmonid fish species for each of three SFK reaches (SFK-A, SFK-B, and SFK-C) and one tributary (SFK 1.190). No results are displayed for SFK-D and SFK-E, because transects were not established in those reaches. SFK-D is located directly below Frying Pan Lake and contains comparatively little spawning habitat. SFK-E extends above Frying Pan Lake and there have been relatively few anadromous salmonids found in this reach. There were 43 transects used in the analysis (Table 15.1-24): 19 in SFK-A, 12 in SFK-B, six in SFK-C, and six in Tributary SFK 1.190. Transect weighting, in accordance with the frequency of representative habitat types in a reach, are summarized in Table 15.1-10. The time series reflects the total habitat area of a reach for each day during the period a given species and life stage is present.

Specific flow ranges corresponding to 90 percent or more of the maximum modeled habitat areas in each reach are shown for anadromous and non-anadromous fish categories in Table 15.1-25. The ranges vary as a factor of the results from different species as reported in Appendix 15.1C, Tables 40 and 46.

Results of the habitat time series analyses for Chinook salmon, coho salmon, and sockeye salmon spawning and juvenile life stages are summarized for SFK-A, SFK-B, and SFK-C on Figure 15.1-47. These results focus on the total habitat area versus river flow relationship, because this parameter provides reach-scale estimates of the total amount of habitat for a given species and life stage available under different flow conditions (refer to Appendix 15.1C for tributary results, other flow-related parameters, and individual transect results). The results, expressed in acres, are presented graphically as a time series of habitat based on average flow conditions in the reaches. The time series analyses are presented graphically by reach in terms of the total habitat area that would occur on a daily basis during the time period in which an individual species and life stage may be present. For example, juvenile Chinook salmon may be present year-round, while adult spawning is limited from July through September, as depicted on Figure 15.1-47. This evaluation is useful for comparing the relative amounts of habitat provided for a given species and life stage under different flow conditions.

The total estimated amount of habitat area (spawning and juvenile), expressed in acres, for each species available within a given reach, based on the median daily flows over the respective time periods for each life stage, is displayed in the chart inserts on Figure 15.1-47. The results indicate there can be substantial variability in habitat amounts on a daily basis, in response to changes in flow. This variation is most evident during flow transitional periods. For example, during the spring-summer periods when flows are declining there is a general increase in juvenile habitat. Similarly, during the summer-fall period when flows increase there is a general increase in spawning habitat. The absence of juvenile habitat in SFK-C from February through April reflects the ephemeral nature of this reach, when a portion of the stream typically flows subsurface and the channel bed becomes dry. The overall process used in deriving the time series and the detailed results for these species, as well as other species and life stages, and for Tributary SFK 1.190, are presented in Appendix 15.1C.

As noted for the NFK, the time series analysis represents a first step in evaluating how baseline flow conditions influence fish habitats temporally and spatially. Additional time series analyses based on wet year, dry year, and average year conditions, as well as a series of associated habitat duration curves for each reach are provided in Appendix 15.1C (Tables 42, 45, and 48, and Figures 55 through 57, 61 through 63, and 67 through 69). Appendix 15.1C also contains estimates of total habitat area by species and life stage provided in the entire SFK (all reaches combined) during an average water year (Appendix 15.1C, Table 73).

SFK Special Habitat Features

Special features found within the SFK that likely influence the existing distribution and abundance of fish include seeps and springs, intermittent flow reaches, lakes and ponds, and beaver ponds, as discussed below.

Seeps and Springs. A comprehensive survey of seeps and springs in the SFK was performed in 2005 and 2006, and the surface water expression of these features was plotted in Figure 9.1-4 of Chapter 9, Section 9.1. There was a large concentration of seeps and springs upstream of Frying Pan Lake and in the central portion of the SFK, along the upper portion of SFK-B. Seeps and springs add to river flow and moderate

stream temperatures in both summer and winter. Summer water temperatures decline on the order of 41ºF (5ºC) in the mainstem between SFK-C and SFK-B, shortly downstream of the confluence with Tributary SFK 1.190 (Appendix 15.1E). Temperatures continued to decline downstream through the length of both SFK-C and SFK-B with the input of cool water seeps and springs.

Such surface water expressions may offer groundwater upwelling sites that anadromous salmonids favor in selecting spawning locations. The upper portion of SFK-B was heavily influenced by groundwater upwelling and was extensively used for spawning. These cool water sources may also provide summer rearing habitats for juvenile fishes. In the winter, these same groundwater upwelling sites may create localized areas of relatively more stable flow and may in fact provide water temperatures that are warmer than ambient winter temperatures. Thus, groundwater upwelling sites may be used as overwintering habitats and maypromote higher salmonid embryo survival.

Intermittent Flow Reaches. A large and variable portion of SFK-C at times exhibits intermittent flows during summer and winter (Chapter 7, Section 7.2, Figure 7.2-5). The severity and duration of low seasonal flow events vary by year. For example, based on flow records from gaging station SK100C during 2007, there was no surface flow in SFK-C for a period of 40 days between early July and early September, 2007. Conversely, the reach did not become completely dry in the summer of 2008. Cessation of flow in winter is more expected due to freezing conditions. When these channels are dry, fish must either move upstream or downstream to areas of flowing water, or become stranded within the influenced reach.

Lakes and Ponds. Lakes and ponds are prevalent in the SFK watershed, consistent with the area's glacial history. The largest named lakes in the watershed include Frying Pan and Chiquita lakes. Most of the lakes and ponds in this watershed are relatively high in the watershed. The largest concentration of lakes and ponds is in the vicinity of the Frying Pan Lake complex adjacent and connected to SFK-E. No adult anadromous species have been recorded spawning along the shore of Frying Pan Lake. However, limited observations of juvenile coho salmon and sockeye salmon in the lake indicate this habitat may have some potential for rearing. Surface water impoundments like Frying Pan Lake and nearby ponds also provide habitat for other stream-dwelling fishes and provide water storage and extended surface water runoff volumes late in the summer period compared to watersheds without such storage.

Beaver Ponds. Beavers can have a substantial influence on channel morphology and hydraulics. Beavers are ubiquitous throughout the NFK, SFK and UT systems and, in some locations, have had a considerable effect on flow and habitat conditions. Analysis of aerial photos indicates that beavers may have built dams spanning the mainstem channel in the headwaters of all three river systems (see Appendix 15.1F). Such structures have resulted in the ponding of water that create a mosaic of small ponds and interconnecting channels. During wildlife surveys in the SFK, 36 beaver colonies were recorded (Chapter 16, Section 16.2, Figure 16.2-20). Beaver ponds in the SFK provide adult spawning and juvenile overwintering habitat for Pacific salmon. Sockeye salmon adults were observed in beaver–created habitat in the SFK watershed. Beaver ponds and small stream channels influenced by groundwater, may provide large amounts of ice-free habitat during winter (Murphy et al., 1989; Collen and Gibson, 2001). In addition, beaver ponds in the SFK were slightly warmer than other habitat types and thus, may represent a more productive habitat as compared to cooler mainstem channel habitat types. This could support increased growth rates of juvenile salmon and more fish per unit area compared with mainstem channel fish (Appendix 15.1D).

SFK Potential Limiting Factors

Habitat features in either short supply or in poor relative condition that may be limiting fish abundance and productivity in the SFK are discussed below.

Velocity Shelter. A general lack of mainstem channel pool habitat, instream cover features, and large woody debris in the SFK results in a lack of velocity shelter for rearing fishes. This condition suggests juvenile rearing may need to rely on off-channel habitats, especially for winter refuge when water temperature and stream flow become quite low. The lack of juvenile winter rearing habitat is evident in the instream flow habitat duration curves (Figure 15.1-47).

Water Temperature. The annual water temperature regime of the SFK is cold, severely restricting rearing conditions. Because fish are cold-blooded species (cannot regulate their body temperature) all metabolism, activity, swimming speed, and behavior are directly linked to ambient water temperature conditions. Cold water restricts active feeding to a brief summer period (late-May to mid-September) when water temperatures exceed 46ºF (8ºC); therefore, productivity of the population is limited as compared to watersheds where the active feeding period is longer (Campbell and Neuner, 1985). This limitation is likely typical of many regional streams.

It is important to note that even within this cold water river, warn water temperatures in the summer months also may be limiting to fish health and productivity. Given the open riparian nature of most of the streams in the SFK watershed, water temperatures warm quickly during the summer months and naturally exceed the ADEC maximum water temperature standard for spawning and incubation of 55ºF (13°C; ADEC, 2009). Exceedences of the spawning and incubation criterion represented 93 percent of the station records reporting peak summer temperatures (June through August) during the study period. Temperatures also exceeded the ADEC maximum water temperature standard for migration routes and rearing areas of 59ºF (15°C; ADEC, 2009) for 76 percent of the summer records, and the ADEC maximum water temperature standard of 68ºF (20°C; ADEC, 2009) for 17 percent of the peak recorded summer temperature values over the study period. The maximum temperatures recorded in the SFK were greater than high temperatures reported for other streams in the region (Table 15.1-8).

Water Quality. Water quality data indicate that the waters of the SFK are soft (Chapter 9, Section 9.1). Soft waters are typically not as productive for fish growth as harder (more mineralized) waters. Low levels of mineralization can influence aquatic productivity, including fish biomass, in comparison to streams with high levels of mineralization (McFadden and Cooper, 1962; Hendrickson et al., 1973; Marshall et al., 1980). Thus, hardness and parameters influencing mineralization (e.g., alkalinity, TDS, conductivity, etc.) can be used as screening level surrogates for stream productivity. This limitation is evident in other streams within the region, as shown in Table 15.1-8.

Soft waters can also increase the acute toxicity of divalent trace metals to aquatic organisms. Toxicity increases inversely to water hardness (Carroll et al., 1979; Pagenkopf, 1983; Pascoe et al., 1986; Davies et al., 1993; Markich and Jeffree, 1994; Meyer et al., 1999). Pagenkopf (1983) provides evidence suggesting metal toxicity to fishes is a function of divalent trace metal attachment to gill surfaces. Markich and Jeffree (1994) and Meyer et al. (1999) imply as hardness increases, divalent calcium ions will bind to the gill surface in lieu of further metal attachment. Thus, metal toxicity is reduced in hard waters compared to soft waters. CALC in Alaska waters for various trace metals are a function of hardness concentrations (ADEC, 2008). Based on water quality data collections for trace metals in the SFK, aluminum, cadmium,

copper, iron, lead, mercury, and zinc exceeded estimated CALCs (Chapter 9, Section 9.1). Of these constituents, the cadmium, copper, lead, and zinc criteria are a function of water hardness. Given the low frequency and limited geographical extent of criteria exceedences, the SFK baseline water quality conditions for trace metals are not regarded as a potential limiting factor to fish production in the watershed. However, the soft waters remain a risk to increased metal toxicity from cadmium, copper, lead, and zinc. Copper and lead had much higher frequencies of exceedences than the other constituents in the SFK. Copper could be regarded as potential natural limiting factor to fish production since the exceedances are spatially correlated to specific locales closer to the general deposit area; this may be especially true in SFK-E upstream of Frying Pan Lake, where copper exceedences were most common. In general, lead is not considered a potetial natural limiting factor to fish production since the exceedances are not seasonally or spatially correlated. However, station UT135A had seven exceedances within eight field visits collected between October 2005 through September 2006. This concentration of lead exceedances suggests some chronic exposure to fish may have occurred.

Generally, nutrient concentrations in SFK were found to be low (Chapter 9, Section 9.1). The production of primary producers is based on a combination of sunlight, temperature, and nutrient availability. At any point in time, one of these factors will limit aquatic productivity. If the availability of nutrients is the concern, the current ratio of nitrogen to phosphorus suggests phosphorus would typically be the limiting nutrient for growth of photosynthetic organisms in the SFK. Should productivity of primary producers become reduced, based on a lack of phosphorus, it is likely secondary consumers and, ultimately, food resources for fish species may become reduced compared to other regional streams.

Stream Flow. Losing stream reaches occur along SFK mainstem reaches downstream of Frying Pan Lake (SFK-D and SFK-C), where surface water infiltrates permeable glacial outwash sediments (Chapter 7, Section 7.2). Portions of these channels go dry and intermittent stream flows are a concern to juvenile fish production. The low taxa richness values reported at Station SK100D in SFK-C (Figure 15.1-46) may reflect intermittent stream flows and imply reduced biological production.

Groundwater. Surface water expression of groundwater can provide considerable benefits to spawning and rearing fish. The distribution of zones of observable groundwater influence is limited to gaining reaches in SFK-A and throughout most of SFK-B. Fish abundance and productivity might be reduced in other locations with lower input of groundwater. As an example, salmon spawning is restricted upstream of SFK-B (Appendix 15.1B, Figures B.9-10, B.9-11, B.9-12, and B.9-13). This location is upstream of the zone of major groundwater influx to surface waters in the reach.

Potential limiting factors will vary for each species and life history stage. For example, anadromous salmonid species with extended freshwater residence time like Chinook, coho, and sockeye salmon, as well as resident salmonid fishes, are typically considered limited by the juvenile rearing life stage. Conversely, species with abbreviated residence time, like chum salmon, are considered spawning-limited in the stream environment. Based on the list of limiting factors above, it is likely the most limiting life-history stage for most of the species is juvenile overwinter rearing and survival.

For chum salmon in the SFK, the abundance and productivity of populations is limited by the amount of viable spawning habitat. This habitat may be restricted, in part, due to the distribution of spawning gravels, as well as the hydrologic regime and groundwater inputs to areas downstream of SFK-C.

SFK Fish Resources/Assemblage

More than 14 different fish species were documented in the SFK from 2004 through 2008 (Table 15.1-26; Figure 15.1-48). This is a minimum number, because some resident fishes (including sculpin, whitefish, and lamprey) were not consistently identified to species during field surveys. Overall, SFK-B had the greatest number (14) of fish species groups, and there was a tendency for the number of species to decrease in the upstream reaches. The species composition in the SFK, as determined during the 5-year study period, was similar to that documented by reconnaissance field efforts in the early 1990s (Buell, 1991; Buell, 1994). Buell's field effort documented 11 species that were common to the study area, only missing rainbow trout, burbot, and lamprey.

The life stage periodicity (reflects the timing of various life stage functions – spawning, egg incubation, fry, juvenile, and adult migration) for anadromous and non-anadromous salmonids is presented on a regional basis in Appendix 15.1A and on a fish study area basis on Figure 15.1-19. Figure 15.1-19 was developed based on a general understanding of local fish populations and refers to the general timing of fish life history stages for the entire aquatic resources study area (Appendix 15.1C). Life history information specific to the SFK watershed is included in the species descriptions below and in Appendix 15.1A.

Several fish species present in the SFK are important to commercial, subsistence, and recreational harvest. Anadromous salmonid fishes from the SFK, along with those from the Wood, Snake, and Igushik rivers and the Nushagak watershed downstream of the SFK, are considered part of the Nushagak Management District. Because no data are available to assess the relative contribution of these SFK fish to the fisheries, district-scale data are provided here as an indication of the importance of these fisheries. Based on a 20-year average (1988 through 2007), the annual commercial harvest for the overall Nushagak District was 52,190 Chinook, 476,508 chum, 28,660 coho, and 4,969,524 sockeye salmon (Jones et al., 2009). Over the same period, the average subsistence harvest was: 13,047 Chinook, 4,461 chum, 5,420 coho, and 26,421 sockeye salmon.

In general, recreational harvest of anadromous salmonids is considerably less than commercial and subsistence harvest. SFK salmon are a part of the Bristol Bay Sport Fish Management Area. In the Bristol Bay Sport Fish Management Area, the average annual recreational harvest for the years 2000 to 2004 was: 10,067 Chinook, 2,108 chum, 13,611 coho, and 12,288 sockeye salmon (Dye et al., 2006). Over the same period, the average annual recreational harvest in the Mulchatna River, into which the SFK eventually drains, was 194 Chinook and 160 sockeye salmon. Data specific to recreational harvest in the SFK are not available; however, it can be assumed that the number would be less than that for the Mulchatna River system.

The following sections describe the fish resources in the SFK by species assemblages under major grouping of anadromous salmonid fishes, non-anadromous (resident) salmonid fishes, and non-salmonid fishes. Data are presented in terms of mainstem channel reaches, off-channel habitat, and tributary waters draining into the mainstem reaches in the SFK. Many of the sampling techniques were not conducive to estimating CPUE, but where sufficient electrofishing or snorkeling data exist from all survey passes, the species assemblages including collections of all life history stages indicate the trends presented in Table 15.1-27.

Furthermore, fish survey results are commonly discussed below using relative fish abundance and fish density metrics. The relative abundance metric, which is expressed as the number of fish per 328 lineal feet (100 meters), is used to describe fish assemblages throughout the watershed and among habitat types. This metric was calculated for each species by summing the total number of fish observed or captured within a given habitat type and dividing it by the total lineal distance, in meters, of the habitat type surveyed; this metric was then multiplied by 100 such that the abundance metric is standardized to 100 meters or 328 feet. The fish density metric, which is expressed as the number of fish per 1,076 sf (100 m^2), is used to assess fish-habitat associations and allows for a direct comparison of fish numbers among habitat types. The fish density metric was calculated in a manner similar to the abundance metric, with habitat area (wetted width times sample length) used in place of sample length. The associated relative fish abundance and fish-habitat association figures represent a summary of the mainstem channel fish abundance and density figures presented in Appendix 15.1B. In Appendix 15.1B, these metrics were calculated separately for the 2004 through 2007 and 2008 study years, as well as for mainstem and tributary habitats. In the Section 15.1 relative abundance and fish-habitat association figures, only mainstem channel data are reported, and the metrics have been calculated by combining the 2004 through 2007 and 2008 data.

SFK Anadromous Salmonid Fishes

Anadromous salmonid fishes represent the most abundant fish taxa in the SFK watershed. The distribution, life history, spawning abundance, relative abundance, and habitat associations of Chinook, chum, coho, and sockeye salmon present in the SFK are discussed in the following sections. The presence of anadromous fish species in the SFK stream reaches, as determined from2004 through 2008 survey data, is presented in Table 15.1-28. The distribution of anadromous fishes based on data from 2004 through 2008, as well as the ADF&G's anadromous stream layer, is depicted on Figure 15.1-49. Anadromous spawning locations are depicted on Figure 15.1-50, while specific spawning locations for each species by reach are provided in Appendix 15.1B.

The seasonal distribution of anadromous salmonids in the SFK watershed appears to be largely dictated by the intermittent flow conditions that often occur in SFK-C. Such conditions create periods of low or no flow within SFK-C, and preclude fish use during those times (Figure 15.1-39, Gage SK100C). Thus, there has been a general lack of adult anadromous fish documented upstream of SFK-C. However, when surface flows are present, low numbers of juvenile anadromous fish have been observed in SFK-C and upstream reaches.

Chinook Salmon. The Chinook salmon distribution in the SFK watershed was restricted to SFK-A through SFK-D (Table 15.1-28, Figure 15.1-48). However, their presence in SFK-D was limited to three juvenile Chinook salmon observations over the study period. Field surveys in SFK-C identified 3 adults in 2005 and a total of 198 juveniles between 2004 and 2008 (Appendix 15.1B, Table B.9-7). The numbers of both juvenile and adult Chinook salmon observations were considerably higher in SFK-A and SFK–B; greater than 40 adults and 16,000 juveniles were observed in SFK-A and SFK-B combined during on-the-ground surveys during the baseline study period.

In general, Chinook salmon fry emerge in the spring and remain in the freshwater rearing habitat until outmigration (Appendix 15.1A). In some populations, juvenile Chinook salmon outmigrate as young-of-the-year fry or as subyearling juveniles. However, this life history pattern is thought to be uncommon in the Bristol Bay basin. Based on length frequency distributions, three age-classes of juvenile Chinook

salmon have been observed in the SFK: young-of-the-year subyearlings (0+), yearlings (1+), and 2+age juveniles. The mean lengths of juvenile Chinook salmon by age-class are shown on Figure 15.1-51. The proportion of juvenile Chinook salmon outmigrating at any age class is unknown. Juvenile Chinook salmon have been documented in the SFK as early as April and as late as November (Appendix 15.1B, Tables B.7-2 and B.8-7).

Based on field surveys, the relative abundance of juvenile Chinook salmon is shown for selected reaches on Figure 15.1-52. In SFK-A, Chinook salmon were the second most abundant salmonid present, with estimates ranging from 325 to 475 fish per 328 feet (100 meters). Chinook salmon were less abundant in SFK-B and SFK-C, ranging from 8 to 124 fish per 328 feet (100 meters) and, in order of species rank, were generally less abundant than coho salmon, arctic grayling, and Dolly Varden in most habitat types (Figure 15.1-52). Juvenile Chinook salmon were predominantly found in the main channel in both fast and slow water habitats.

Densities of Chinook salmon were calculated among the various habitat types that were documented during the 2008 mainstem index surveys in the SFK and among various tributary and off-channel habitat types. In the mainstem SFK, densities ranged from approximately 1 fish per 1,076 sf (100 m^2) in glide, riffle, and pool habitat to approximately 40 fish per 1,076 sf (100 m^2) in glide habitat (Appendix 15.1B). Riffles supported the second greatest observed density of Chinook salmon at 15 fish per 1,076 sf (100 m^2). Within the SFK tributaries, juvenile Chinook salmon observations were limited to Tributaries SFK 1.190.60 and SFK 1.240.10.10, where densities generally ranged from less than 1 fish per 1,076 sf (100 m^2) in fast-water habitats (cascades, riffles, run/glides) to approximately 26 fish per 1,076 sf (100 m^2; Appendix 15.1B, Tables B.8-8 and B.9-8). In the off-channel habitat intensive study area in the SFK, Chinook salmon density was greatest in side channels (approximately 7 fish per 1,076 sf [100 m^2]) and well below 1 fish per 1,076 sf (100 m^2) in other habitat types (Figure 15.1-53).

Aerial surveys for adult Chinook salmon in the SFK were conducted in 2004 through 2008. During the 5-year period, adult Chinook salmon entered the SFK as early as July 5 and were present in the watershed as late as August 23 (Figure 15.1-54). Survey counts peaked each year between July 20 and August 4.

The greatest adult Chinook salmon mean index counts were documented in 2004 with a declining trend evident from 2004 through 2006 (Figure 15.1-54; Figure 15.1-55). There was an order of magnitude decline in SFK Chinook salmon mean index counts from 2004 to 2006, with the greatest decline evident in 2005. The mean index counts were similar in 2006, 2007, and 2008. Chinook salmon numbers also showed a decline over time for the entire Nushagak District (Morstad et al., 2010) and in the Nushagak River (Baker et al., 2009; Table 15.1-15). The greatest reduction in run size at the District scale and in Nushagak River escapement were evident from 2006 to 2007, 2 years later than the greatest observed decline in the SFK.

Reach-specific counts allow for an assessment of the salmon spawner distribution within the SFK watershed. From 2004 through 2008, Chinook salmon spawning was observed only in the lowest three SFK reaches (SFK-A, SFK-B, and SFK-C; Appendix 15.1B). The relative abundance of spawners in SFK-C was very low, with only four spawning locations documented (Appendix 15.1B, Figure B.9-10). In 2008, spawning was documented only in SFK-A and SFK-B (Table 15.1-29; Figure 15.1-56). The mean number of spawners in SFK-A was 186, while SFK-B had a mean count of 58 spawners. Adult Chinook salmon are typically associated with mainstem reaches and require sufficient discharge to complete their upstream migration (Appendix 15.1A); therefore, low flows in and above SFK-C limit the

spawning distribution of this species. In addition, the instream flow habitat analysis indicates a large reduction in the available Chinook salmon spawning habitat in and above SFK-C, compared to SFK-A and SFK-B (Appendix 15.1C, Tables 40, 43, and 46).

Mean index counts were used to provide a perspective of the relative size of salmon runs in the SFK with respect to the Nushagak District and the greater Bristol Bay fishery. Chinook salmon within the Nushagak District, which is comprised of the Wood, Snake, Igushik, and Nushagak rivers, have contributed approximately 81 percent of the total Bristol Bay Chinook salmon catch based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). The total inshore run estimates (harvest and escapement) provided by ADF&G for Nushagak District Chinook salmon between 2004 and 2008 ranged from a low of 123,376 fish in 2007 to a high of 244,793 fish in 2005, with a 5-year average of 188,521 (Morstad et al., 2010; Table 15.1-15). During the same time period, Nushagak River Chinook salmon escapement estimates ranged from 53,344 in 2007 to 163,506 in 2005 and had a 5-year average of 106,131 (Baker et al., 2009). In contrast, the SFK Chinook salmon mean index counts (used as an index of escapement) ranged from 148 in 2007 to 2,155 in 2004 and averaged 711 for the 5-year study period (Table 15.1-15).

Chum Salmon. Chum salmon distributions are generally restricted to low-gradient reaches in a watershed, because their swiming ability is not as strong as other anadromous salmonids (Appendix 15.1A). The distribution of chum salmon, from SFK-A through SFK-C (Table 15.1-28), is consistent with general observations for this species and, on a more local scale it may also be influenced by the cessation of groundwater upwelling im the mainstem above SFK B and the intermittent flow conditions within SFK-C. While few adult chum salmon have been observed in SFK-C, their presence suggests juveniles must also be present during certain periods of time (contingent on the occurrence of surface water flows).

Chum salmon fry emergence generally occurs in late winter and early spring before ice break-up (Appendix 15.1A). Chum salmon are known to seek spawning areas influenced by groundwater upwelling; therefore, ice-free conditions would presumably be present at the time of fry emergence. Observed juvenile chum salmon in the SFK comprise only young-of-the year (age 0+) life history stages in the SFK (Figure 15.1-51). Juvenile chum salmon were recorded in low numbers from April through September in SFK-B and April to July in SFK-A (Appendix 15.1B, Tables B.7-2 and B.8-7). The lack of juvenile chum salmon observations in late summer likely reflects their rather brief period of stream residence prior to outmigration. This finding is consistent with the general life history patterns of chum salmon (Groot and Margolis, 1998), where juveniles are thought to overwinter in estuarine waters.

The relative abundance of juvenile chum salmon is shown on Figure 15.1-52. Overall, abundances of juvenile chum salmon were low in the SFK, with the highest abundance found in SFK-A (1.5 fish per 328 feet [100 meters]). This abundance was two to three orders of magnitude less than both Chinook and coho juvenile salmon and about one order of magnitude less than juvenile sockeye salmon.

Because of their abbreviated residence time, little information was collected regarding juvenile chum salmon habitat associations in the SFK. However, observed juvenile chum salmon were generally found in mainstem run/glide and riffle habitat (Appendix 15.1B, Figures B.7-7 and B.8-8a) and were also documented in off-channel habitats, particularly beaver ponds, in very low numbers and densities (Figure 15.1-53). The observed density in off-channel beaver ponds was less than 1 fish/per 1,076 sf (100 m^2). Juvenile chum salmon were not observed during the 2008 mainstem index surveys, nor in SFK tributaries (Appendix 15.1B).

Aerial surveys for adult chum salmon in the SFK were conducted in 2004 through 2008. During the 5-year period, adult chum salmon entered the SFK to spawn as early as July 5 and were found during surveys as late as August 25 (Figure 15.1-57). Peak counts occurred each year between July 11 and July 26. No adult chum salmon were observed in the SFK in 2004.

Adult chum salmon were the least abundant Pacific salmon species in the SFK, with mean index counts between 71 and 353 salmon (Table 15.1-15; Figure 15.1-58). Overall, the SFK chum salmon mean index counts remained relatively stable (between 225 and 353 salmon) from 2005 through 2008, except for a mean index count of 71 salmon in 2007. At the Nushagak District scale, chum salmon runs increased between 2004 and 2006 and then declined through 2008 (Morstad et al., 2010; Table 15.1-15). Nushagak River chum salmon escapement showed a trend similar to the District total inshore run, although an increase in escapement was observed in 2008 (Baker et al., 2009).

Reach-specific counts allow for an assessment of the salmon spawner distribution within the SFK. From 2004 through 2008, spawning chum salmon were observed in SFK-A, SFK-B, and in the very lower portion of SFK-C (Appendix 15.1B). The spawning abundance and distribution analysis using the 2008 aerial survey data revealed that chum salmon spawn predominantly in SFK-B (Table 15.1-29; Figure 15.1-56). The mean number of spawning chum salmon in SFK-B was 158, while SFK-A had a mean count of 86 spawning salmon. Chum salmon spawning is likely restricted to the lower portion of the SFK due to abundance of groundwater influence there as well as the intermittent flow conditions in SFK-C.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the SFK with respect to the Nushagak District and the greater Bristol Bay fishery. Chum salmon within the Nushagak District, which is comprised of the Wood, Snake, Igushik, and Nushagak rivers, contributed approximately 51 percent of the total Bristol Bay catch based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). The total inshore run estimates (commercial catch and escapement) provided by ADF&G for the Nushagak District chum salmon between 2004 and 2008 ranged from a low of 754,053 fish in 2004 to a high of 1,901,238 fish in 2006, with a 5-year average of 1,191,993 (Morstad et al., 2010; Table 15.1-15). During the same time period, Nushagak River chum salmon escapement estimates ranged from 161,483 in 2007 to 661,002 in 2006 and had a 5-year average of 377,724 (Baker et al., 2009). In contrast, the SFK chum salmon mean index counts (used as an index of escapement) ranged from 71 in 2007 to 353 in 2008 and averaged 246 for the 5-year study period.

Coho Salmon. Coho salmon are distributed in all five reaches of the SFK (Table 15.1-28). Although adult coho salmon have not been observed above SFK-C, small numbers of juvenile coho salmon were found in SFK-D and SFK-E, upstream of Frying Pan Lake (Appendix 15.1B). These fish are either the result of undocumented spawning in these reaches, or the upstream movement of juveniles from downstream reaches.

In general, coho salmon fry emerge between mid-March and May (Appendix 15.1B). Length frequency data indicate four age-classes of coho salmon juveniles occur in the SFK: subyearling (0+), yearling (1+), 2+age, and 3+age juveniles. Mean fork lengths for each age class are shown on Figure 15.1-51. In many watersheds throughout their range, juvenile coho salmon overwinter in freshwater and outmigrate as 1+ fish, with some juveniles residing for up to 2 years in freshwater (Appendix 15.1A). In the SFK, the proportion of coho salmon juveniles outmigrating as 1+, 2+, or 3+ fish is currently unclear, although the length data indicate some 3+ age coho salmon remain in the SFK. Juvenile coho salmon have been documented in the SFK as early as April and as late as November (Appendix 15.1B, Table B.7-2 and B.8-

7). Juvenile coho salmon were found in SFK-A and SFK-B during the winter surveys, indicating that these reaches provide overwintering habitat.

The relative abundance of juvenile coho salmon is shown for selected reaches on Figure 15.1-52. In SFK-A, SFK-B, and SFK-C, coho salmon were the most abundant salmon, with estimates ranging from 5 to approximately 590 fish per 328 feet (100 meters). The highest abundance of coho salmon was in SFK-A. In SFK-D and SFK-E, closer to the upstream extent of their distribution and where spawning has not been documented, coho salmon were much less abundant (1 to 25 fish per 328 feet [100 meters]).

Densities of coho salmon were calculated among the various habitat types that were documented during the 2008 mainstem index surveys in the SFK and among various tributary and off-channel habitat types. In the mainstem SFK, densities were greatest in glide habitats at approximately 130 fish per 1,076 sf (100 m^2; Appendix 15.1B). Pools and riffles also supported coho salmon; densities ranged from approximately 2 to 70 fish per 1,076 sf (100 m^2) in pool habitat and from approximately 4 to 17 fish per 1,076 sf (100 m^2; Appendix 15.1B). Within the SFK tributaries, the greatest densities of juvenile coho salmon generally were in backwater and glide habitats, where densities of greater than 100 fish per 1,076 sf (100 m^2) were observed (Appendix 15.1B, Tables B.8-8 and B.9-8). In the off-channel habitat intensive study area in the SFK, coho salmon densities were greatest in side channels and percolation channels (approximately 22 and 33 fish per 1,076 sf [100 m^2], respectively; Figure 15.1-53). Coho salmon were also present in beaver ponds and isolated pools, but at lesser densities (approximately 1 to 7 fish per 1,076 sf [100 m^2]).

Aerial surveys for adult coho salmon in the SFK were conducted annually from 2004 through 2008. During 5-year period, adult coho salmon entered the SFK to spawn as early as July 30 and were present as late as November 16 (Figure 15.1-59). Peak counts occurred between September 5 and October 2.

Coho salmon mean index counts in the SFK were only slightly greater than those for chum salmon. Over the study period, mean index counts ranged from 121 to 494 salmon (Table 15.1-15; Figure 15.1-60). Similar to coho salmon in the NFK, they showed a generally increasing trend over the years with the exception of a decline in 2007. This decline in mean index counts was also seen in chum salmon and, to some extent, Chinook salmon in the SFK. Total run and escapement estimates were not available for Nushagak District and Nushagak River coho salmon; however, it is worth noting that catch statistics for the Nushagak District also showed a substantial decline in coho salmon numbers in 2007 (Morstad et al., 2010; Table 15.1-15).

Reach-specific counts allow for an assessment of the salmon spawner distribution within the watershed. During the 2008 aerial surveys, coho salmon were observed spawning in SFK-A, SFK-B, and SFK-C (Table 15.1-29; Figure 15.1-56). The greatest numbers of spawning coho salmon occurred in SFK-B, with a mean survey count of 235 adults. SFK-A had the second greatest number of spawning adults, with an annual mean survey count of 186 adults. In addition, 49 spawning coho salmon were observed in SFK-C aerial surveys, with a mean survey count of eight adults. Adult coho salmon migrate into the watershed and spawn later than the other salmon species. Due to fall rains, river flows within the SFK for coho salmon are generally higher than for other spawning salmon, providing more frequent access for coho salmon to and above SFK-C. As a result, coho salmon have a broader spawning distribution within SFK-C compared to other anadromous salmon species. Nevertheless, the distribution of coho salmon upstream of SFK-B is influenced by low and intermittent flows in SFK-C, especially during the early period of their spawning migration (Figure 15.1-39, Gage SK100C). Coho salmon spawning sites were also

documented in three SFK tributaries: SFK 1.130 (the outlet to Chiquita Lake), SFK 1.190, and SFK 1.240 (Appendix 15.1B).

Mean index counts were used to provide a perspective of the relative size of salmon runs in the SFK with respect to the Nushagak District and the greater Bristol Bay fishery. Coho salmon within the Nushagak District, which is comprised of the Wood, Snake, Igushik, and Nushagak rivers, contributed approximately 31 percent of the total Bristol Bay catch, based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). Nushagak District run estimates and Nushagak River escapement estimates for coho salmon were not available. However, commercial catch for coho salmon in this district from 2004 through 2008 ranged from 29,578 fish in 2007 to a high of 73,889 fish in 2008, with a 5-year average of 47,603 (Morstad et al., 2010; Table 15.1-15). Although not directly comparable, the SFK coho salmon mean index counts (used as an index of escapement) ranged from 121 in 2007 to 494 in 2008 and averaged 309 for the 5-year study period (Table 15.1-15).

Sockeye Salmon. During the study period, sockeye salmon were distributed throughout four of the five mainstem reaches of the SFK: SFK-A, SFK-B, SFK-C, and SFK-E (Table 15.1-28). Adults were observed only in the lowermost SFK reaches (SFK-A, SFK-B, and SFK-C), whereas juveniles were documented in SFK-E in addition to the three lower SFK reaches. The number of juvenile sockeye salmon in SFK-E was low. Four juveniles were observed in Frying Pan Lake (SFK-E) in July 2004, and one was observed in the mainstem SFK in August 2008 (Appendix 15.1B). Sockeye salmon also were documented throughout Tributary SFK 1.190 and in the lower reaches of Tributary SFK 1.240.

Sockeye salmon fry typically emerge in early spring, either under the ice or within groundwater influenced ice-free areas (Appendix 15.1A). Within 2 to 3 weeks after emergence, juveniles tend to move downstream or into lake habitat. Length frequency data indicate that two age classes of sockeye salmon juveniles occur in the SFK: subyearling (0+ age) and yearling (1+ age). Mean lengths for each age class are shown on Figure 15.1-51. The proportion of juvenile sockeye salmon outmigrating at any age class is unknown. Juvenile sockeye salmon were observed during winter fish surveys in April, October, and November in SFK reaches with considerable groundwater input (SFK-A and SFK-B; Appendix 15.1B). These data indicate that SFK-A and SFK-B provide overwintering habitat for juvenile sockeye salmon.

The relative abundance of juvenile sockeye salmon is shown for selected reaches on Figure 15.1-52. Far fewer juvenile sockeye salmon were found than Chinook and coho salmon, but slightly more than chum salmon. This pattern is consistent with the abbreviated riverine residence time of both juvenile sockeye and chum salmon. Sockeye salmon were most abundant in SFK-B with estimates greater than 20 fish per 328 feet (100 meters).

Densities of sockeye salmon were calculated among the various habitat types that were documented during the 2008 mainstem index surveys in the SFK and among various tributary and off-channel habitat types. In the mainstem SFK, densities were consistently low across habitat types, ranging from less than 1 fish per 1,076 sf (100 m^2) in pool, riffle, and run/glide habitats to a high of approximately 2 fish per 1,076 sf (100 m^2) in riffle habitat (Appendix 15.1B). Within the SFK tributaries, juvenile sockeye salmon observations were limited to Tributaries SFK 1.240 and SFK 1.1.260, where densities generally ranged from less than 1 to approximately 3 fish per 1,076 sf (100 m^2) in pool, riffle, and run/glide habitats(Appendix 15.1B, Table B.9-8). In the off-channel habitat intensive study area in the SFK, sockeye salmon densities were largely similar to those in the mainstem SFK (less than 1 to approximately 2 fish per 1,076 sf [100 m^2]; Figure 15.1-53).

Aerial surveys for adult sockeye salmon in the SFK were conducted from 2004 through 2008. During this 5-year period, adult sockeye salmon entered the SFK to spawn as early as July 5 and adults were still present as late as September 18 (Figure 15.1-61). Aerial survey counts peaked between July 23 and August 3 in all years.

Sockeye salmon runs were the most stable of the four anadromous salmon runs in the SFK watershed during the study period. This pattern was similar to the observed annual variation in sockeye salmon runs in the NFK. However, SFK sockeye salmon mean index counts were, on average, more than two times greater than those in the NFK (Figure 15.1-34; Figure 15.1-62). SFK sockeye salmon were the most abundant of the Pacific salmon spawning in the SFK from 2005 to 2008, with mean index counts ranging from 1,019 to 1,791 fish (Table 15.1-15). Sockeye salmon total run estimates provided by ADF&G for the Nushagak District were also relatively stable compared to other Bristol Bay districts and to other species (Morstad et al., 2010). In the Nushagak District, the peak sockeye salmon run from 2004 through 2008 occurred in 2006 (Morstad et al., 2010; Table 15.1-15). In the Nushagak River, sockeye salmon escapement estimates peaked 1 year earlier, in 2005, when escapement was nearly twice that observed in other years during the 5-year study period (Baker et al., 2009). These peaks in total run and escapement estimates were not evident in the SFK sockeye salmon mean index counts (Table 15.1-15).

Reach-specific counts allow for an assessment of the salmon spawner distribution within the watershed. The distribution of spawning sockeye salmon in the SFK was limited to the lowest three reaches (SFK-A through SFK-C; Appendix 15.1B). In 2008, the greatest abundance of spawning fish occurred in SFK-B, with a mean survey count of 1,530 adults, and 12,237 spawning observations over the course of the 2008 survey period (Table 15.1-29; Figure 15.1-56). SFK-A had a mean survey count of 815 spawning adults, and only 1 spawning adult was found in SFK-C. As with the other anadromous salmonids in the SFK watershed, the distribution of spawning sockeye salmon is likely influenced by low or intermittent flows that can occur in SFK-C during late July or early August (Figure 15.1-39; Gage SK100C). The presence of juvenile sockeye salmon in SFK-E suggests that either limited spawning may occur within that reach, contingent on flow conditions, or that some juveniles move upstream into SFK-E following emergence.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the SFK with respect to the Nushagak River District and the greater Bristol Bay fishery. Sockeye salmon within the Nushagak District, which is comprised of the Wood, Snake, Igushik, and Nushagak rivers, contribute approximately 20 percent of the total Bristol Bay catch, based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). Total inshore run estimates (commercial catch and escapement) provided by ADF&G for the Nushagak District sockeye salmon from 2004 through 2008 ranged from a low of 8,248,738 fish in 2004 to a high of 15,738,137 fish in 2006, with a 5-year average of 11,023,703 (Morstad et al., 2010; Table 15.1-15). During the same time period, Nushagak River sockeye salmon escapement estimates ranged from 492,000 in 2004 to 1,049,000 in 2005 and had a 5-year average of 620,000 (Baker et al., 2009). In contrast, the SFK sockeye salmon mean index counts (used as an index of escapement) ranged from 1,019 in 2005 to 1,791 in 2008 and averaged 1,422 for the 5-year study period (Table 15.1-15).

SFK Non-anadromous (Resident) Salmonid Fishes

Although non-anadromous salmonid fishes are overall less abundant than anadromous salmonids in the SFK, they represent an important component of the fish community in this watershed. Rainbow trout are particularly important with respect to recreational fisheries for resident salmonids. The catch rate for

rainbow trout in the Mulchatna drainage averaged 3,993 fish per year from 2000 to 2004 (Dye et al., 2006). Subsistence catches of resident salmonids ranges from 55 to 92 percent of the households (depending on species) in the towns of Iliamna, Newhalen, and Nondalton (Table 15.1-18; Fall et al., 2006).

The distribution, life history, relative abundance, and habitat associations of each of the four non-anadromous salmonid taxa present in the SFK are discussed below. The mean length of arctic grayling, Dolly Varden, and rainbow trout by age class captured in the SFK is presented on Figure 15.1-63.

Arctic Grayling. Juvenile and adult arctic grayling were observed within all five (SFK-A through SFK-E) of the SFK mainstem reaches (Table 15.1-30). Adults were recorded during the months of May through September, with no discernable pattern in timing or reaches they inhabit (Appendix 15.1B, Tables B.7-2, B.8-7, B.9-7, B.10-6, and B.11-7). Juvenile grayling were observed between the months of April through November in multiple reaches.

Few data are available to describe stream-specific life history characteristics of arctic grayling in the SFK. As noted for the NFK and elsewhere in their range, adults overwinter in lakes or mainstem channels and migrate to upstream tributaries to spawn in May and June (Appendix 15.1A). Following spawning, adults may return to lakes or mainstem channels or remain in upstream tributaries for a summer feeding season.

The relative abundance of arctic grayling is shown on Figure 15.1-52. In the lower two reaches, grayling abundance ranged from approximately 1 to 39 fish per 328 feet (100 meters). Estimated abundance increased in the upper reaches, with estimates ranging from 5 to 45 fish per 328 feet (100 meters) in SFK-C, 20 to 280 fish per 328 feet (100 meters) in SFK-D, and 3 to 100 fish per 328 feet (100 meters) in SFK-E.

Overall, arctic grayling were found in the mainstem channel, side channel, and off-channel habitats in the SFK, as well as in tributaries (Appendix 15.1B). The density data presented for SFK-E on Figure 15.1-64 indicate that arctic grayling were observed in both fast and slow water habitats, with densities ranging from approximately 4 to 16 fish per 1,076 sf (100 m^2) in slackwaters and run/glides, respectively (Figure 15.1-64). Among the SFK tributaries, arctic grayling were most dense in slow-water habitats (approximately 20 to 30 fish per 1,076 sf [100 m^2] in slackwaters and pool habitat (Appendix 15.1B, Figures B.8-9, B.9-9, and B.11-9b). Arctic grayling were also present in beaver ponds and side channels at relatively low densities (Figure 15.1-65).

Dolly Varden. Like arctic grayling, Dolly Varden were distributed throughout the SFK (Table 15.1-30). Juvenile fish were observed in all five reaches, and adults in all but SFK-D. Both anadromous and non-anadromous populations of Dolly Varden are thought to occur in the Bristol Bay region, (Appendix 15.1A). While Dolly Varden has been included herein as a non-anadromous species, little is known about their stream-specific life history patterns. As noted for the NFK watershed, a complexity of life histories can exist within the non-anadromous populations, with variations in spawning frequency, migration timing, and selection of overwintering sites. In the SFK, adults have been observed in July, August, and September, while juveniles have been seen in April through November (Appendix 15.1B, Tables B.7-2, B.8-7, B.9-7, B.10-6, and B.11-7).

Based on field surveys, the relative abundance of Dolly Varden is shown for selected reaches on Figure 15.1-52. Dolly Varden abundance ranged from less than 1 to 55 fish per 328 feet (100 meters). The

pattern of Dolly Varden abundance in tributaries was also variable. Estimates of abundance in SFK-C tributaries were generally less than 10 fish per 328 feet (100 meters), while estimates in tributaries to SFK-E and SFK-B were variable (Appendix 15.1B, Tables B.8-8b, B.9-8b, and B.11-8b). These values ranged from less than 1 to greater than 35 fish per 328 feet (100 meters) for SFK-E and approximately 10 to 230 fish per 328 feet (100 meters) in SFK-B.

Similar to trends in the NFK, Dolly Varden were associated with a broad variety of habitats, including mainstem channel, side channel, and off-channel habitats, as well as SFK tributaries (Appendix 15.1B). The highest densities in the SFK-E mainstem were observed in backwater habitats affiliated with the mainstem channel (as high as 34 fish per 1,076 sf [100 m^2]; Figure 15.1-64). Densities in pool, riffle and run/glide habitat were much lower (less than 3 fish per 1,076 sf (100 m^2]). In SFK tributaries, the greatest observed Dolly Varden densities were in backwater and riffle habitats, at densities of approximately 35 to 45 fish per 1,076 sf (100 m^2; Appendix 15.1B, Figures B.8-9, B.9-9, and B.11-9b). Among off-channel habitats, Dolly Varden densities were generally low, with beaver ponds supporting the highest density of fish at 1.25 fish per 1,076 sf (100 m^2; Figure 15.1-65).

Rainbow Trout. The distribution of rainbow trout (adults and juveniles) in the SFK was limited to SFK-A, SFK-B, and SFK-E (Table 15.1-30). Both adults and juvenile life history stages were observed in each of the three reaches. Adult rainbow trout were documented in the SFK in July, August and September, while juveniles were observed in April through September (Appendix 15.1B, Tables B.7-2, B.8-7, and B.11-7).

The relative abundance of rainbow trout was low, ranging from less than 1 to approximately 3 fish per 328 feet (100 meters) in SFK-A and SFK-B, to 35 fish per 328 feet (100 meters) in SFK-E (Figure 15.1-52). The density of rainbow trout in mainstem habitat types in SFK-E ranged from less than 1 fish per 1,076 sf (100 m^2) in run/glide habitats to approximately 9 fish per 1,076 sf (100 m^2; Figure 15.1-64). In riffles, the observed density was approximately 6 fish per 1,076 sf (100 m^2). Among the SFK tributary habitats, rainbow trout densities were low (approximately 3 fish per 1,076 sf [100 m^2] in slackwater habitat; Appendix 15.1B, Figure B.8-9). Only three rainbow trout juveniles were observed in SFK off-channel habitats.

Whitefish. In the SFK, the whitefish species group may include humpback whitefish, least cisco and round whitefish. Adults of this species group were distributed in SFK-A, SFK-B, and SFK-C, whereas, juvenile observations were limited to SFK-C (Table 15.1-30). In the early 1990s, least cisco and humpback whitefish were documented in the SFK (Buell, 1994).

SFK Non-Salmonid Fishes

Non-salmonid fishes found in the SFK watershed included burbot, northern pike, sculpin, stickleback, and lamprey (Table 15.1-31). Northern pike are valued as a subsistence and sport fish to local communities. Information regarding the distribution, relative abundance, and habitat associations of these non-salmonid species groups in the SFK is provided below.

Burbot. The SFK is the only watershed in the study area where burbot (*Lota lota*) has been observed. The known distribution of burbot in the SFK includes SFK-B and SFK-C (Table 15.1-31). Only small groups (three or fewer individuals) of juvenile burbot were collected.

Northern Pike. In the SFK, adult northern pike were largely associated with lake habitats, including Frying Pan Lake, as well as in Tributaries 1.260, 1.370, and 1.380 with connectivity to other lakes. Pike were the predominant fish species found in Frying Pan Lake (HDR, 2006). Northern pike were also documented in reaches SFK-B through SFK-E (Table 15.1-31). Observations included both juveniles and adults in all reaches except for SFK-B, where only juvenile fish were observed. A small number of adults were observed in glide and pool habitats in mainstem and tributary reaches above and below Frying Pan Lake. Northern pike juveniles occupied both fast and slow water habitats in mainstem and tributary reaches where they were observed in pool, riffle, and run/glide habitats. Northern pike abundance estimates for the mainstem SFK ranged from less than 1 to approximately 4 fish per 328 feet (100 meters; Figure 15.1-64). Northern pike were more abundant in SFK-E in association with Frying Pan Lake habitats than in the downstream reaches.

Sculpin. Both juvenile and adult sculpin have been documented in all reaches of the SFK (Table 15.1-31). Although sculpin were not identified to species, slimy sculpin and coastrange sculpin are known to inhabit the Bristol Bay basin (Appendix 15.1A). Slimy sculpin have been documented by Buell (1994) and ADF&G (2006b) in the SFK.

In the mainstem SFK, the relative abundance of sculpin ranged from approximately 1 fish per 328 feet (100 meters) to 290 fish per 328 feet (100 meter; Figure 15.1-64). Sculpin were also found in tributaries within SFK-B, SFK-C, and SFK-E, where abundances ranged from approximately 1 to 230 fish per 328 feet (100 meters; Appendix 15.1B, Figures B.8-8b, B.9-8b, and B.11-8b).

Sculpin were captured in both fast and slow water habitats. In SFK-E, densities in the mainstem ranged from less than 1 to approximately 3 fish per 1,076 sf (100 m^2; Figure 15.1-33). Habitat associations and densities in SFK tributaries were similar, particularly in SFK-C and SFK-E tributaries (Appendix 15.1B, Figures B.9-9 and B.11-9b). The greatest sculpin densities occurred in pool, riffle, and run/glide habitats in the SFK-B tributaries, with densities ranging from approximately 20 to 40 fish per 1,076 sf (100 m^2; Appendix 15.1B, Figure B.8-9). In off-channel habitats, sculpin were found in beaver ponds at a density of approximately 1 fish per 1,076 sf (100 m^2; Figure 15.1-65).

Stickleback. In the SFK, stickleback have been documented in all reaches except SFK-D (Table 15.1-31). Consistent with Buell (1994), current observations in the SFK include both ninespine stickleback and threespine stickleback. Abundance and density estimates of stickleback were generally low. In the mainstem SFK, abundances were less than 2 fish per 328 feet (100 meters; Figure 15.1-52). Densities were less than 1 fish per 1,076 sf (100 m^2) in mainstem channel and off-channel habitats (Figure 15.1-64; Figure 15.1-65). Stickleback densities in the SFK tributaries were similarly low and ranged from less than 1 to 4 fish per 1,076 sf (100 m^2) among slackwater, pool, riffle, and run/glide habitats (Appendix 15.1B, Figures B.8-9, B.9-9, and B.11-9b).

Lamprey. Observations of lamprey in the SFK have been limited to the two lowermost reaches (SFK-A and SFK-B; Table 15.1-31). Only juvenile lamprey were observed, and these fish were not identified to species.

SFK Watershed Synthesis

In the SFK, all anadromous salmon spawning occurred downstream of Frying Pan Lake. However, most of the spawning occurred in the lowermost reaches of SFK-A and SFK-B. The spawning reach analysis

data showed spawning Chinook salmon were more prevalent in the large river reaches of SFK-A, whereas chum, coho, and sockeye salmon spawning was more abundant in SFK-B. In general, these spawning distributions were in contrast with the instream flow habitat results that indicated substantially more anadromous spawning habitat should be available in SFK-A compared to SFK-B and SFK-C. Other parameters, including hydrology and temperature, appeared to be related to spawning distributions. The species distributions of adult sockeye and chum salmon in these reaches showed a direct relationship between spawning and areas with inflow from groundwater, seeps, or springs. These salmon spawned only in the vicinity of groundwater both on a localized scale within a reach and among reaches. Furthermore, summertime surface water temperatures in the SFK increase in Frying Pan Lake and remain relatively high until the upstream end of SFK-B, where Tributary SFK 1.190 enters the mainstem channel. Due to cool water inflows from the tributary, as well as numerous spring and seeps, water temperatures at this location begin to decline and continue to decrease until the middle of SFK-B. This cold water upwelling area and the area immediately downstream supported the majority of salmon spawners in the SFK.

The observation that anadromous spawning was largely limited to the lower three reaches of the SFK reflected the unreliable habitat conditions associated with the large and variable ephemeral section of the river located in the middle of SFK-C. In some years, such as 2007, the ephemeral section completely dries for an extended time during salmon spawning periods and the lack of flow can create a fish passage barrier to upstream habitats. However, in high flows years, such as 2008, the ephemeral section remained fully wetted and anadromous salmon had access to the entire length of SFK-C. Adult chum, coho, and sockeye salmon expanded their distributions upstream in 2008, with small numbers of fish spawning in the available habitat in SFK-C. While chum and sockeye spawning locations were limited to the downstream portion of SFK-C, coho salmon spawned sporadically throughout the entire reach.

Based on mean index counts, the SFK supported the second largest run of Chinook and chum salmon among the three watersheds in the study area. The mean index counts of coho salmon in the SFK and NFK were similar. Both were substantially less than the UT coho salmon index counts. The sockeye salmon mean index counts in the SFK were consistently two to three times larger than those in the NFK, yet, in 3 out of 5 years, they were an order of magnitude less than the UT counts. In the other two years (i.e., 2006 and 2007), the SFK sockeye salmon mean index counts were within an order of magnitude as compared to those in the UT; this was the result of a dramatic decrease in the UT sockeye salmon mean index counts during these years.

The distributions of river-rearing juvenile Pacific salmon species followed similar patterns as the adult spawning distributions. The highest abundance and diversity of juvenile salmon were found in the lower two reaches. Very few Chinook salmon were found upstream of SFK-C. However, during high water years, small numbers of coho and sockeye salmon were documented in SFK-C and further upstream including in habitats above Frying Pan Lake. This expansion in juvenile distribution is, in general, consistent with spawning further upstream during high water years, but also implies that juvenile salmon may move upstream from spawning areas for rearing purposes in the SFK.

Juvenile Chinook salmon were prominent in mainstem channel, fast-water habitats that dominate the lower reaches of the SFK. Juvenile coho salmon were more widely dispersed and were found in a variety of habitat types. Coho salmon were observed at the highest densities among all salmonids in off-channel habitats. The wide distribution and broad habitat use for juvenile coho salmon is consistent with the

finding that coho salmon were the most abundant juvenile salmon documented in the SFK, and that four juvenile age classes of coho salmon were identified in SFK habitats.

Ten non-anadromous salmonids and non-salmonid fishes were present in the SFK, making this watershed the most species rich fish assemblage in the mine study area. A second distinction of the SFK fish assemblage was the presence of both burbot (SFK-B and SFK-C) and lamprey (SFK-A and SFK-B) species. These species were not present in any other watersheds. Unlike the anadromous salmonids, the stream resident fish species were distributed in low numbers throughout the SFK. Arctic grayling and Dolly Varden were the most abundant and broadly distributed of the resident fishes.

Overall, SFK-B supported the largest diversity of species and highest relative abundance of the fishes documented over the study period. This reach also supported the greatest amount of predicted available habitat for most species and life stages present. Tributary 1.190, which had abundant springs located along the stream margins, contributed river flow to SFK-B (Chapter 9, Section 9.1). As mentioned above, this reach was marked by a gradual decline in water temperatures to the midpoint of the reach, followed by a gradual increase in temperatures downstream. Similar to the NFK, the recorded high temperatures in the SFK were several degrees higher than those reported for other streams in the region.

Intermittent stream flows were a concern in mainstem channel of SFK-C during dry years. The river in this reach dries from the upstream and downstream ends inwards towards the middle, resulting in isolated pools that have the potential to strand fish and/or dewater incubating eggs. In addition, ephemeral flows were documented in three SFK tributaries: SFK 1.260, SFK 1.330, and SFK 1.370. These periodically dry habitats could potentially limit fish production on a local level.

The ephemeral reach area in SFK-C marks the beginning of a section of the SFK where the habitat transitions from that supportive of a Pacific salmon-dominated fish assemblage to habitat that supports populations of stream rearing and resident fishes. This transitional zone continues into SFK-E and upstream to the upper end of Frying Pan Lake. Below the transitional zone, water temperatures are cooler due to the large groundwater influence in SFK-B. Gravels and cobbles dominate the substrates. The overall abundance and diversity of fishes is greatest in these downstream habitats.

Within the transitional zone, river flow is unstable and ephemeral in some years during summer and winter low flow periods. Near the upstream end of the transitional zone the stream channel flattens and widens to create Frying Pan Lake. The stream gradient is reduced and substrates contain higher proportions of fines than elsewhere in the watershed. Macroinvertebrate richness is reduced in the transition zone due to river flow and channel conditions.

Upstream of the transition zone, the SFK returns to a river channel and stream gradient increases. Stream temperatures are influenced by numerous seeps and springs within tributary subwatersheds. Although cooler than the water temperatures within the transitional zone, the thermal regime in the mainstem headwater reaches is warmer than river reaches downstream of SFK-C. Fish abundance and diversity increase upstream of the transitional zone but are still reduced compared to the lowermost reaches, SFK-A and SFK-B. The fish assemblage in this headwater area is dominated by resident fish species.

Frying Pan Lake is at the upstream end of the transition zone and at the downstream end of SFK-E. This shallow lake helps to attenuate flows to downstream reaches and has a substantial warming effect on surface waters in the transition zone. It also provides habitat for a population of northern pike, an

aggressive predator of smaller fishes—including juvenile salmon and resident fishes. The environmental conditions within Frying Pan Lake are suboptimal for juvenile salmonids and, as such, may pose limitations on fish passage and influence the overall distribution of salmonid fishes throughout the SFK watershed.

The data collected during the study period show the preponderance of fish spawning and rearing in the SFK was associated with areas where there was a surface water expression of groundwater. These areas of detectable groundwater influence were widespread throughout the lower two reaches, with areas of higher groundwater influence noted in SFK-B. In areas where groundwater influx was not prevalent, fish diversity and abundance were reduced.

15.1.6.3 Upper Talarik Watershed

UT Watershed Overview

The UT watershed drains an area of about 135 mi^2 (350 km^2) and is part of the Iliamna Lake watershed (24,719 km^2) which drains into Bristol Bay through the Kvichak River (Figure 15.1-5). From its headwaters, which are located in the immediate vicinity of the Pebble Deposit (Figure 15.1-66), the UT flows in a south-southwesterly direction for about 39 miles (62 km) where it enters Iliamna Lake. The UT drainage represents about 1.7 percent of the Kvichak River system and 0.3 percent of the entire Bristol Bay drainage basin (Table 15.1-2).

The highest elevation in the UT drainage is Pig Mountain (elevation 2,809 ft; 856 meters) while the lowest elevation is at the stream outlet to Iliamna Lake (elevation about 46 ft; 14 meters). The watershed is bounded by a series of low, isolated mountain blocks: Koktuli Mountain to the west, Groundhog Mountain to the north, Dalton Mountain to the northeast, and a long unnamed ridge that separates the UT drainage from the Newhalen River to the east. The northwestern surface water drainage divide between the NFK and UT is inconspicuous. A general map of 1,518 aquatic resources study site locations in the UT sampled during the baseline period is shown on Figure 15.1-67.

UT Aquatic Habitats

This section describes the physical, chemical, and biological components of aquatic habitat in the UT. These habitat components are discussed in distinct sections to facilitate comparison among watersheds.

UT Physical Conditions

Fish-bearing waters in the mainstem UT have been divided into seven stream reaches with distinct hydrology, geology, and channel characteristics (Figure 15.1-66; Table 15.1-32). The seven reach designations (UT-A through UT-G) progress from downstream to upstream along the length of the mainstem UT. As discussed in Section 15.1.1, tributaries were assigned to the mainstem reach into which they flowed, and off-channel habitats were assigned to a mainstem reach based on their proximity to the mainstem channel. Photographs depicting representative channel characteristics of each reach are provided in Photos 15.1-22 through 15.1-28.

Channel Morphology. The UT is primarily a single-thread, gravel-bedded channel that is relatively straight along much of its length, except where the river valley and floodplain widens and multiple

channels have formed. The channel slopes of the UT were generally steeper than those of both the NFK and SFK. Channel slopes ranged from 0.1 to 2.0 percent with a mean of 0.5 percent in the FG study sites. As in the NFK and SFK, large woody debris was scarce in the upper portion of the UT watershed due to a general lack of forest vegetation in the riparian zone. The lower reaches were associated with larger trees, and large woody debris was more prevalent.

Alluvial transport and deposition were common within most of UT-B and the entire length of UT-A. Within these areas, high flows typically overflow the banks, and channels were bordered by relatively wide floodplains. Associated riparian zones (some supporting large trees), wetland complexes, and off-channel habitat extended well beyond the stream banks. Large woody debris was present within these sections of the UT and served to create and maintain habitat diversity.

In the upper third of UT-B and in UT-C, the river channel was low gradient, contained, and flowed through a relatively narrow (1,300 to 2,600 feet [400 to 800 meters]) valley bottom, bordered by low hills to the west and carved glacial deposits to the east.

UT-D, UT-E, and the lower half of UT-F were classified as alluvial floodplain channels that formed by re-working glacial outwash deposits. Multiple former stream terraces and colluvial slopes were evident where the current stream channel has downcut through glacial outwash and lacustrine deposits. Steep side slopes represent sediment sources where the channel impinges against the valley walls. Tributaries flowing in from the isolated mountain blocks were varied with high-gradient, contained, moderate-gradient, mixed control, and alluvial fan channels. Large woody debris was relatively sparse within these reaches due to a lack of source trees from the riparian zone.

In the upper half of UT-F and UT-G, the channel flowed across deep glacial lacustrine deposits. Channels tended to contain higher levels of fine sediment than elsewhere in the UT. The downstream limits of the lacustrine deposits were in the same area as the downstream limit of mainstem beaver dam construction. Channel elevations in UT-E, UT-F, and UT-G were comparable to elevations in the NFK and SFK.

Hydrology. The hydrology of the mine study area is described in detail in Chapter 7, Section 7.2. Like the NFK and SFK watersheds, the baseline hydrology of the UT mainstem channel was strongly influenced by climate, geology, and groundwater influx. Stream flows were driven by runoff from spring snowmelt and summer/fall rains. Base flows tended to remain high in both winter and late summer due to groundwater storage.

Similar to the NFK and SFK, flow in the UT generally has two peaks (Figure 15.1-68). The first peak occurs during the spring snowmelt season (with the majority of the snowmelt runoff typically occurring in late April and May), while the second peak occurs during the fall rainy season (late August to November). The key difference in timing between the UT and the NFK and SFK peak flows is a slightly earlier spring freshet in UT. The peaks in the UT are separated by two low flow seasons: a summer low flow (with minimum flows typically occurring in August), and a winter low flow (with minimum flows typically occurring in late March to mid April). The mean annual flow in UT was 232 cfs (6.6 m^3/s) during water years 2005 through 2008 at Hydrology Gage UT100B (USGS Gage No. 15300250). This discharge is equivalent to a mean annual unit runoff of 36.5 inches (92.7 centimeters) from the 86.2 mi^2 (223 km^2) drainage area at the gage. The lowest most gage in the UT watershed (UT100-APC3) recorded a mean annual discharge of 382 cfs (10.8 m^3/s) during the 2008 water year.

The UT hydrograph showed a pronounced groundwater influence. Most of the groundwater contributions to the UT mainstem come from aquifers located within the UT basin. In addition, the inter-basin transfer from the SFK has a localized effect in the receiving tributary (Tributary UT 1.190) and contributes a modest portion of the baseflow to the UT mainstem below the tributary confluence. Gage data indicated that approximately 22 cfs (0.6 m^3/s) of flow entered the UT watershed through cross-watershed transfer of groundwater from the SFK (Chapter 7, Section 7.2). The groundwater flowed eastward from the SFK, likely along flow paths formed by former glacial meltwater channels, and emerged in Tributary UT 1.190. Because of this groundwater influence, Tributary UT 1.190 exhibited a much higher unit runoff (i.e., flow per unit watershed area) and a much more stable hydrograph than other streams in the UT watershed (Figure 15.1-68). Flow records indicated the downstream portion of UT-F (downstream from Hydrology Gage UT100D) and UT-D also received groundwater inflow from UT aquifers, and portions of these reaches remained ice-free during winter months.

Water Temperature. Water temperatures in the UT watershed begin to seasonally warm in May and June and generally peak in July and August. Temperatures cool down during September and October and stay near freezing from November through April. A series of temperature plots during calendar year 2007 at select UT gages is shown on Figure 15.1-69 to indicate the general thermal regime across the watershed. More detailed temperature data, as well as a description of the SNTEMP flow-sensitive surface water temperature models that were developed and calibrated using these baseline data, are included in Appendix 15.1E.

During the study period, the longitudinal thermal regime of the UT was characteristic of a surface water system influenced by groundwater and coldwater tributary inflow (Figure 15.1-70). In particular, there was a broad distribution of distinct groundwater effects in the middle reaches of the UT and within Tributary UT 1.190. Water temperatures, combined with flow records, indicate that the UT received groundwater inflow in the downstream portion of UT-F (downstream from Hydrology Gage UT100D) that was relatively cool in the summer and relatively warm in the winter. Similarly, UT-D received relatively cool groundwater inflow in the summer.

While water temperatures remained at or near freezing during the winter season throughout most of the UT, there was greater variability in water temperatures during the summer (Appendix 15.1E). The daily temperature range during the summer months (June, July, and August) for all monitoring gages and years for the UT watershed is provided in Table 15.1-33. The instantaneous minimum and maximum daily temperatures ranged from a low of 36.5ºF (2.5ºC) at the most upstream monitoring site UT100E in UT-G in 2006 and 2007 to a high of 65.8ºF (18.8ºC) at station UT100D in UT-F during 2004.

Instantaneous summertime maximum temperatures did not exceed the ADEC maximum water temperature standard for aquatic life of 68ºF (20ºC; ADEC, 2009) during the 2004 through 2008 period (Table 15.1-33). Summer temperature data indicate that the ADEC maximum water temperature standard for spawning and egg and fry incubation of 55ºF (13ºC; ADEC, 2009) was exceeded for 59 percent of the instantaneous temperature records, and the ADEC maximum water temperature standard for migration routes and rearing areas of 59ºF (15ºC; ADEC, 2009) was exceeded for 44 percent of maximum records during the study period. Overall, the thermal regime of the UT was relatively cooler than the NFK and SFK. This thermal difference may be due, in part, to the prominent groundwater influence and the lack of any lake-related warming effects in the UT, such as those evident with Frying Pan Lake in the SFK and Big Wiggly Lake in the NFK.

The thermal regime of the UT has had an influence on the behavior, metabolism, and growth of fish, and their use of specific fish habitats. In the study area where freezing and low water temperatures are a concern, fish would likely be attracted to groundwater-fed channels during the winter, because these sites represent areas of stable flows and relatively warm water temperatures (Leman, 1993; Ebersole et al., 2003). The middle mainstem river reaches and Tributary UT 1.190 may offer thermal refuge to winter rearing life history stages. Similarly, the groundwater influence in these reaches during summer months may offer enhanced thermal conditions for summer rearing compared to other mainstem and tributary areas.

Mainstem Channel Habitat. The baseline frequencies of habitat types (e.g., pool, riffle, run/glide, etc.) in the mainstem UT, as determined from remote sensing techniques, were itemized in detail at the reach level in Appendix 15.1B and summarized at the watershed scale, as shown on Figure 15.1-71. Results of mesohabitat mapping indicate that riffle habitat was dominant and run/glide habitat was the subdominant habitat type in UT-A, UT-B, and UT-G. Conversely, run/glide was dominant, and riffles comprised a secondary component of habitat composition in UT-C, UT-D, UT-E and UT-F. Pool habitats represented a substantial proportion of the habitat composition only within UT-E (12 percent) and UT-F (22 percent). The frequency of pool habitats remained less than 10 percent by area in all other UT reaches. The frequency of USFS channel types is shown on Figure 15.1-72. This map is based on the overall lengths of channel segments identified during the field surveys along selected reaches in the UT. The USFS channel type codes and descriptions are provided in Table 15.1-5. Channel type frequencies and results of the Tier 3 habitat surveys indicated that riffle habitat dominated the morphology of the UT mainstem and tributary channels (Figure 15.1-73).

The prevalence of riffle and run/glide habitats within the UT indicates the potential for substantial quantities of spawning habitat. This concept was confirmed as part of adult salmon surveys and redd measurements (see *UT Fish Resources* section below). However, given the lack of pools and slackwater habitat features in the mainstem river in UT-A through UT-D, both summer and winter rearing habitats may be limited in the mainstem and more prevalent in off-channel habitats.

Pacific salmon require cold, clear, and well oxygenated water with gravel- to cobble-sized substrates for spawning. The quality of spawning gravels was good, based on grain size analysis of bulk substrate samples collected from three locations in the UT. The concentrations of fine sediment size fractions that have been related to embryo survival (less than 0.03 inches [0.84 millimeters]) and fry emergence (less than 0.25 inches [6.4 millimeters]) were all well below levels considered harmful (over 12 and 20 percent, respectively; after Shirazi et al., 1981; Lotspeich and Everest, 1981; Chapman and McLeod, 1987; Reiser and White, 1988; Kondolf, 2000). Refer to Appendix 15.1F for detailed results of the spawning gravel analysis.

Off-channel Habitat. Like the NFK and SFK, the UT system contained a substantial amount of off-channel habitat comprised of side channels, alcoves, percolation channels, beaver ponds, beaver pond outlet channels, and isolated ponds (Figure 15.1-74). The UT off-channel habitat study sites contained an estimated 13 acres of off-channel habitat. The area and frequency by off-channel habitat type is presented in Table 15.1-34.

Beaver ponds were the most frequently observed and most expansive off-channel habitat type in the UT. These complexes typically include a combination of ponded areas and associated outlet channels that create both pool and slow moving run/glide type habitats. Off-channel habitats provide a variety of

habitats that may be used by a diverse assemblage of fish species and life stages at a range of mainstem channel flows. Isolated ponds are unique among off-channel habitat types in that they are only connected to the mainstem channel during overbank flows.

Survey results showed many of the off-channel habitat sites were hydrologically connected to the mainstem channel via surface inflow at less than bankfull flows (approximately 550 cfs [16 m^3/s]; Appendix 15.1D). A subsample of 11 off-channel habitat sites shows that connectivity is established between the off-channel habitat sites and the mainstem channel at flows that ranged from 39 to 455 cfs (1.1 to 12.9 m^3/s; Table 15.1-35). See Appendix 15.1D for more information regarding the off-channel flow study.

UT Chemical Habitat Conditions

A comparison of various water quality parameters reported in the mine study area and those reported for other water quality studies in the region is provided in Table 15.1-8. These parameters include water temperature, DO, specific conductance, pH, turbidity, alkalinity, and hardness. Similar to the NFK and SFK, the UT watershed was characterized by generally good water quality conditions that support habitat for a range of salmonid and non-salmonid fishes. Overall, the reported values in the UT were similar to those for other watersheds in the region (Table 15.1-8). The notable exceptions include: a maximum water temperature of 60.3ºF (15.7ºC), which is slightly greater than the maxima reported for most of the other watersheds; a low DO minimum of 2.7 mg/L; and a broader range of reported values for pH, alkalinity, and water hardness. Some concentrations were found to vary as a factor of flow conditions, location within the watershed, or season (Chapter 9, Section 9.1).

In addition to the water quality parameters included in Table 15.1-8, concentrations of trace elements, cyanides, and nutrients were determined as part of the surface water quality studies in the mine study area (Chapter 9, Section 9.1). Natural exceedences of estimated freshwater aquatic life criteria were observed in the UT for aluminum (total and dissolved), iron (total), copper (total and dissolved), lead (total and dissolved), cadmium (total and dissolved), silver (total), and WAD cyanide. The number of samples exceeding these criteria was less than 1 percent for dissolved aluminum, dissolved cadmium, and total silver, less than 2 percent for total iron, total cadmium, dissolved lead, and WAD cyanide, less than 3 percent for dissolved copper, less than 8 percent for total copper, less than 9 percent for total lead, and approximately 22 percent for total aluminum. For aluminum, the majority of naturally occurring concentrations above criteria were primarily from one mainstem location (UT100E) and three tributary locations (UT135A, UT138A, and UT141A). The tributary where UT141A is located flows through the eastern portion of the general deposit area, and the other two are located nearby. The majority of these samples were collected between April and June. The majority of the copper exceedences occurred at station UT146A, which is located on a tributary that flows through the eastern portion of the deposit. No pattern was evident for lead exceedences, suggesting that these naturally elevated concentrations may be the result of localized sources throughout the watershed. Mean nutrient concentrations were generally low.

UT Aquatic Macroinvertebrates

Studies of both periphyton and aquatic invertebrate communities in the UT were conducted in conjunction with those for the NFK and SFK, and detailed results are described in Section 15.2. Because of the

importance of macroinvertebrates as both food for fish and as indicators of stream health, annual results of the macroinvertebrate studies in the UT are summarized for June sampling efforts below.

The macroinvertebrate taxa richness of three sample sites (UT-100B, UT-100C, and UT-100D) is shown on Figure 15.1-75. Similar to the NFK and SFK, taxa richness was determined for June sampling efforts in 2004, 2005, and 2007 using two different collection methods: the ASCI kick net and Surber methods. Taxa richness ranged from a low of 15 taxa at UT-100C in 2007 (Surber method) to a high of 26 taxa at UT-100B in 2004 and 2007 and in UT-100C in 2004 (ASCI method; Figure 15.1-75). The results across the 3 years of sampling for UT-100B and UT-100D indicate reduced taxa richness in 2005. In all years, the mean taxa richness was generally similar among all three sites, which are located in reaches UT-C, UT-D, and UT-F.

The macroinvertebrate communities in the UT were largely composed of midge larvae (Family Chironomidae) and EPT taxa. The contribution of chironomids at the three sample sites ranged from 29 percent at UT-100D in 2005 (Surber method) to 91 percent at UT-100C in 2007 (ASCI method; Figure 15.1-75). For EPT taxa, percentages ranged from 4 percent at UT-100D in 2004 (ASCI method) to 35 percent at UT-100B in 2007 (ASCI method). The macroinvertebrate communities at all sites were dominated by chironomids in all years.

UT Habitat/Flow Relationships

This section presents the results of instream flow habitat modeling and time series analyses computed for various salmonid fish species for each of five UT mainstem river reaches (UT-B, UT-C, UT-D, UT-E and UT-F) and for one tributary (UT 1.190). No results are presented for UT-A or UT-G, because transects were not established in these reaches. UT-A is the most downstream reach that extends into Iliamna Lake and receives substantial tributary (UT 1.60) and accretion flow. UT- G is the most upstream reach and is contained within the immediate area of the Pebble Deposit. There were 40 transects used in the analysis (Table 15.1-36): five in UT-B, seven in UT-C, seven in UT-D, 10 in UT-E, six in UT-F, and five in Tributary UT 1.190. Transect weighting, in accordance with the frequency of representative habitat types in a reach, are summarized in Table 15.1-10. The time series reflect the total habitat area of a reach for each day during the period a given species and life stage is present.

Specific flow ranges corresponding to 90 percent or more of the maximum modeled habitat areas in the five UT reaches are shown for anadromous and non-anadromous fish categories in Table 15.1-37. The ranges vary as a factor of the results from different species as reported in Appendix 15.1C, Tables 52 through 66.

Results of the habitat time series analyses for Chinook salmon, coho salmon, sockeye salmon, and rainbow trout spawning and juvenile life stages for UT-C, UT-D, UT-E, and UT-F are summarized on Figure 15.1-76. These results focus on the total habitat area versus river flow relationships, because this parameter provides reach-scale estimates of the total amount of habitat for a given species and life stage available under different flow conditions (refer to Appendix 15.1C for tributary results, other flow-related parameters, and individual transect results). The results, expressed in acres, are presented graphically as a time series of habitat based on average flow conditions in the reaches. The time series analyses are presented graphically by reach in terms of the total habitat area that would occur on a daily basis during the time period the time period in which an individual species and life stage may be present. For example, juvenile Chinook salmon may be present year-round, while adult spawning is limited from July through

September, as depicted on Figure 15.1-76. This evaluation is useful for comparing the relative amounts of habitat provided for a given species and life stage under different flow conditions.

The total estimated amount of habitat area (spawning and juvenile), expressed in acres, for each species available within a given reach, based on the median daily flows over the respective time periods for each life stage, is displayed on Figure 15.1-76. The results indicate there can be substantial variability in habitat amounts on a daily basis, in response to changes in flow. This variation is most evident during flow transitional periods. For example, during the spring-summer period when flows are declining there is a general increase in juvenile habitat. Similarly, during the summer-fall period when flows increase there is a general increase in spawning habitat. The overall process used in deriving the time series and the detailed results for these species, as well as other species and life stages, and for Tributary UT 1.190, are presented in Appendix 15.1C.

The time series analysis represents a first step in evaluating how UT baseline flow conditions influence fish habitats temporally and spatially. Additional time series based on wet year, dry year, and average year conditions, as well as a series of associated habitat duration curves for each reach are provided in Appendix 15.1C (Tables 54, 57, 60, 63,and 66, and Figures 79 through 81, 85 through 87, 91 through 93, 97 through 99, and 103 through 105). The appendix also contains estimates of total habitat area by species and life stage provided in the entire UT (all reaches combined) during an average water year (Appendix 15.1C,Table 73).

UT Special Habitat Features

Special features found within the UT that likely influence the existing distribution and abundance of fish include seeps and springs, intermittent flow reaches, lakes and ponds, and beaver ponds are discussed below.

Seeps and Springs. A comprehensive survey of seeps and springs in the UT was performed in 2005 and 2006, and the surface water expression of these features was plotted on Figure 9.1-4 in Chapter 9, Section 9.1. There was an abundance of seeps and springs throughout the UT among the tributaries draining the Koktuli Mountains, as well as the hills and divides along the entire western boundary of the watershed and along the mainstem UT. Seeps and springs were also prevalent along Tributaries UT 1.190 and UT 1.310. Seeps and springs add to river flow and moderate stream temperatures in both summer and winter. Summer water temperatures declined on the order of 36ºF (2ºC) in the mainstem between UT-F and UT-E and between UT-D and UT-C, immediately downstream of the confluence with Tributary UT 1.190. Stream temperatures remained cool with the input of seep and spring water throughout the length of the UT downstream through UT-A (Figure 15.1-70).

Such surface water expressions may offer groundwater upwelling sites salmonid fishes favor for selecting spawning locations. In addition, these cool water sources are a benefit to summer rearing for juvenile fishes. Seeps and springs also offer temperature moderation in the mainstem and tributary reaches in the winter such that portions of the watershed remain ice-free and survival of incubating embryos maybe enhanced compared to frozen stream sections.

Intermittent Flow Reaches. There were no mainstem UT reaches temporarily exhibiting seasonal surface water flow cessation during the study period (Chapter 7, Section7.2, Figure 7.2-5). Drainages in

the UT have considerable groundwater contributions that maintain base stream flows in most channels in the watershed.

Lakes and Ponds. Lakes and ponds were prevalent in the UT. Most were concentrated along the eastern boundary of the watershed, with the largest concentration along the long unnamed ridge that separates the UT drainage from the Newhalen River to the east. A large lake was located east of the headwaters of Tributary UT 1.60 (First Creek) and a series of kettle ponds and lakes occurred east of UT-D and UT-E. Adult coho and sockeye spawning was observed in a small lake associated with Tributary UT 1.350.20 as well as in beaver ponds in the UT. Surface water impoundments of this nature provide habitat for other stream-dwelling fishes and provide water storage and extended surface water runoff volumes late in the summer period compared to watersheds without such storage.

Beaver Ponds. Beavers can have a considerable influence on channel morphology and hydraulics. Beavers were ubiquitous throughout the NFK, SFK, and UT watersheds, and in some locations have had a considerable effect on flow and habitat conditions. Analysis of aerial photos indicated that beavers built dams that spanned the mainstem channel in the headwaters of all three river systems (see Appendix 15.1F). Such structures resulted in the ponding of water that created a mosaic of small ponds and interconnecting channels. During wildlife surveys in the UT, 51 beaver colonies were recorded (Chapter 16, Section 16.2, Figure 16.2-20). Beaver ponds were found in off-channel habitat areas throughout the UT active valley. Beaver ponds in the UT provide adult spawning and juvenile overwintering habitat for Pacific salmon. Coho and sockeye salmon were reported spawning in beaver-created habitats in the UT watershed. Elsewhere it has been documented that beaver ponds and small, groundwater-influenced stream channels provide ice-free fish habitat during winter (Murphy et al., 1989; Collen and Gibson, 2001). In addition, beaver ponds in the UT were slightly warmer than other habitat types and thus, may represent a more productive habitat as compared to mainstem channel habitat types. This could support increased growth rates of juvenile salmon and more fish per unit area compared with mainstem channel fish (Figure 15.1-77; Appendix 15.1D).

UT Potential Limiting Factors

Habitat features in either short supply or in poor relative condition that may be limiting fish abundance and productivity are discussed below.

Velocity Shelter. A general lack of mainstem channel pool habitat, instream cover features, and large woody debris in the UT results in low levels of velocity shelter for rearing fishes. This condition indicates juvenile rearing may need to rely on off-channel habitats, especially for winter refuge when water temperature and stream flows become low. The lack of juvenile winter rearing habitat was evident in the instream flow habitat duration curves (Figure 15.1-46).

Water Temperature. The annual water temperature regime was cold in the UT and cooler than in either the NFK or SFK. This thermal regime restricts rearing conditions and growth potential. Because fish are cold-blooded species (cannot regulate their body temperature), all metabolism, activity, swimming speed, and behavior are influenced by ambient water temperature conditions. Cold water restricts active feeding to a brief summer period (mid-May to mid-September) when water temperatures exceed 46ºF (8ºC); therefore, productivity of the population is limited as compared to watersheds where the active feeding period is longer (Campbell and Neuner, 1985). This limitation is likely typical of many regional streams.

Notable for this cold water river, the warmer water temperatures in the summer months also may be limiting to fish health and productivity. Given the open riparian nature of most of the streams in the UT watershed, water temperatures warm quickly during the summer months and naturally exceed ADEC maximum water temperature standard for spawning and incubation of 55ºF (13°C; ADEC, 2009). Exceedences represented 59 percent of the station records reporting peak summer temperatures (June through August) during the baseline period. Water temperatures also exceeded the ADEC maximum water temperature standard for migration routes and rearing areas of 59ºF (15°C; ADEC, 2009) for 44 percent of the summer records. None of the instantaneous maximum summer temperature records exceeded the ADEC maximum water temperature standard of 68ºF (20°C; ADEC, 2009) over the study period. Maximum temperatures in the UT are more like other regional streams than the NFK or SFK (Table 15.1-8).

Water Quality. Water quality data indicate that the waters of the UT are soft (Chapter 9, Section 9.1). Soft waters are typically not as productive for fish growth as harder (more mineralized) waters. Low levels of mineralization can influence aquatic productivity, including fish biomass, in comparison to streams with high levels of mineralization (McFadden and Cooper, 1962; Hendrickson et al., 1973; Marshall et al., 1980). Thus, hardness and similar measures of mineralization (e.g., alkalinity, TDS, conductivity, etc.) can be used as screening level surrogates for stream productivity. This limitation is typical of other regional streams, as summarized in Table 15.1-8.

Soft waters can also increase the acute toxicity of divalent trace metals to aquatic organisms. Toxicity increases inversely to water hardness (Carroll et al., 1979; Pagenkopf, 1983; Pascoe et al., 1986; Davies et al., 1993; Markich and Jeffree, 1994; Meyer et al., 1999). Pagenkopf (1983) provides evidence suggesting metal toxicity to fishes is a function of divalent trace metal attachment to gill surfaces. Markich and Jeffree (1994) and Meyer et al. (1999) imply as hardness increases, divalent calcium ions will bind to the gill surface in lieu of further metal attachment. Thus, metal toxicity is reduced in hard waters compared to soft waters. CALC in Alaska waters for various trace metals are a function of hardness concentrations (ADEC, 2008). Based on water quality data collections for trace metals in the UT, total and dissolved concentrations of aluminum, cadmium, copper, and lead, and total concentrations of iron and silver occasionally exceeded CALCs (Chapter 9, Section 9.1). Of these six metals, the copper, cadmium, lead, and silver criteria are a function of water hardness. Given the low frequency and limited geographical extent of criteria exceedences, the UT baseline water quality conditions for trace metals are not regarded as a potential limiting factor to fish production in the watershed. However, the soft waters remain a risk to increased metal toxicity from cadmium, copper, lead, and silver. Lead and copper had much higher frequencies of exceedences than the other constituents in the UT and could be regarded as a potential natural limiting factors to fish production in some locales; this may be especially true in the vicinity of the Pebble Deposit, where copper exceedences were most common.

Generally, nutrient concentrations in the UT were found to be low (Chapter 9, Section 9.1). The production of primary producers is based on a combination of sunlight, temperature, and nutrient availability. At any point in time, one of these factors will limit aquatic productivity. If the availability of nutrients is the concern, the current ratio of nitrogen to phosphorus suggests phosphorus would typically be the limiting nutrient for growth of photosynthetic organisms in the UT. Should productivity of primary producers become reduced, based on a lack of phosphorus, it is likely secondary consumers and, ultimately, food resources for fish species in the UT may become reduced compared to other regional streams.

Generally, nutrient concentrations in the UT were found to be low (Chapter 9, Section 9.1). The production of primary producers is based on a combination of sunlight, temperature, and nutrient availability. At any point in time, one of these factors will limit aquatic productivity. If the availability of nutrients is the concern, the current ratio of nitrogen to phosphorus suggests phosphorus would typically be the limiting nutrient for growth of photosynthetic organisms in the UT. Should productivity of primary producers become reduced, based on a lack of phosphorus, it is likely secondary consumers and, ultimately, food resources for fish species in the UT may become reduced compared to other regional streams.

Groundwater. Surface water expression of groundwater can provide considerable benefits to spawning and rearing fish. The distribution of zones of observable groundwater influence included UT-D and the lowermost portion of UT-F, as well as in Tributary UT 1.190. Fish abundance and productivity might be reduced in other locations with a lower input of groundwater.

Potential limiting factors will vary for each species and life history stage. For example, anadromous salmonid species with extended freshwater residence time like Chinook, coho, and sockeye salmon, as well as resident salmonid fishes, are typically considered limited by the juvenile rearing life stage. Conversely, species with abbreviated residence time, like chum salmon, are considered spawning-limited in the stream environment. Based on the list of limiting factors above, it is likely the most limiting life-history stage for most of the species is juvenile overwinter rearing and survival.

For chum salmon in the UT, the abundance and productivity of populations is limited by the amount of viable spawning habitat. This habitat may be restricted, in part, due to the distribution of spawning gravels, as well as the hydrologic regime and groundwater inputs to areas downstream of UT-D.

UT Fish Resources/Assemblage

More than 12 different fish species were documented in the UT from 2004 through 2008 (Table 15.1-38). This is a minimum number, because some resident fishes (including sticklebacks, sculpin, and whitefish) were not consistently identified to species during the field surveys. Overall, species numbers remained relatively constant within most reaches, with the greatest number of species (11) found in UT-C and UT-D (Figure 15.1-78). Only four species were found in the headwater reach (UT-G). With a few exceptions, the species composition found during the study period was similar to that documented by reconnaissance field efforts in the early 1990s (Buell, 1991; Buell, 1994). The exceptions included the finding of northern pike by Buell (1994), and the documentation of Chinook, chum, and pink salmon, and whitefish in the UT as part of the study. These differences were most likely due to differences in survey methods and the areas surveyed.

The life stage periodicity (reflects the timing of various life stage functions – spawning, egg incubation, fry, juvenile, and adult migration) for anadromous and non-anadromous salmonids is presented on a regional basis in Appendix 15.1A and on a fish study area basis on Figure 15.1-19. Figure 15.1-19 was developed based on a general understanding of local fish populations and refers to the general timing of fish life history stages for the entire aquatic resources study area (Appendix 15.1C). Life history information specific to the UT watershed is included in the species descriptions below and in Appendix 15.1A.

Many fish species present in the UT are important to commercial, recreational, and subsistence harvest. Anadromous salmonid fishes from the UT, along with those from the from the Alagnak and Naknek rivers and the Kvichak watershed downstream of the UT, are considered part of the Naknek-Kvichak Management District. Because no data are available to assess the relative contribution of these UT fish to the fisheries, district-scale data are provided here as an indication of the importance of these fisheries. Based on a 20-year average (1988 through 2007), the annual commercial harvest for the overall Naknek-Kvichak District was 3,359 Chinook, 190,082 chum, 6,680 coho, and 8,159,760 sockeye salmon (Jones et al., 2009). Over the same period, the average annual subsistence catch was 1,342 Chinook, 852 chum, 1,186 coho, and 78,980 sockeye salmon.

In general, recreational harvest of anadromous salmonids is considerably less than commercial and subsistence harvest. UT salmon are a part of the Bristol Bay Sport Fish Management Area. In the Bristol Bay Sport Fish Management Area, the average annual recreational harvest for the 2000 to 2004 time period was: 10,067 Chinook, 2,108 chum, 13,611 coho, and 12,288 sockeye salmon (Dye et al., 2006). Over the same period, the average annual recreational harvest in the Kvichak River, into which the UT eventually drains, was 91 Chinook and 1,495 sockeye salmon. Data specific to recreational harvest in the UT are not available; however, it can be assumed that the number would be less than that for the Kvichak River system.

The following sections describe the fish resources in the UT by species assemblages under major grouping of anadromous salmonid fishes, non-anadromous (resident) salmonid fishes, and non-salmonid fishes. Data are presented in terms of mainstem channel reaches, off-channel habitat, and tributary waters draining into the mainstem reaches in the UT. Many of the sampling techniques were not conducive to estimating CPUE, but where sufficient electrofishing or snorkeling data exist from all survey passes, the species assemblages including collections of all life history stages indicate trends, as presented in Table 15.1-39.

Furthermore, fish survey results are commonly discussed below using relative fish abundance and fish density metrics. The relative abundance metric, which is expressed as the total number of fish encountered per 328 lineal feet (100 meters), is used to describe fish assemblages throughout the watershed and among habitat types. This metric was calculated for each species by summing the total number of fish observed or captured within a given habitat type and dividing it by the total lineal distance, in meters, of the habitat type surveyed; this metric was then multiplied by 100 such that the abundance metric is standardized to 100 meters or 328 feet. The fish density metric, which is expressed as the number of fish per 1,076 sf (100 m^2), is used to assess fish-habitat associations and allows for a direct comparison of fish numbers among habitat types. The fish density metric was calculated in a manner similar to the abundance metric, with habitat area (wetted width times sample length) used in place of sample length. The associated relative fish abundance and fish-habitat association figures represent a summary of the mainstem channel fish abundance and density figures presented in Appendix 15.1B. In Appendix 15.1B, these metrics were calculated separately for the 2004 through 2007 and 2008 study years, as well as for mainstem and tributary habitats. In the Section 15.1 relative abundance and fish-habitat association figures, only mainstem channel data are reported, and the metrics have been calculated by combining the 2004 through 2007 and 2008 data.

UT Anadromous Salmonid Fishes

Anadromous salmonid fishes (Chinook, chum, coho, sockeye, and pink salmon) were the most abundant and widely distributed fish taxa in the UT watershed. The distribution, life history, spawning abundance, relative abundance, and habitat associations of Chinook, chum, coho, and sockeye salmon present in the UT are discussed in the following sections. Due to the infrequent observations of pink salmon (336 total fish observed on four dates; see below), their presence and distribution in the UT watershed is only briefly discussed. The presence of anadromous fish species in the UT reaches, as determined from 2004 through 2008 survey data, is shown in Table 15.1-40. The distribution of anadromous fishes based on data from 2004 through 2008, as well as the ADF&G's anadromous stream layer, is depicted on Figure 15.1-79. Anadromous salmon spawning areas are depicted on Figure 15.1-80, while specific spawning locations for each species and reach are provided in Appendix 15.1B.

Chinook Salmon. The distribution of Chinook salmon in the UT extends from UT-A to UT-F, comprising nearly the entire length of the watershed (Figure 15.1-79). Both adult and juvenile Chinook salmon have been documented in every reach from UT-A through UT-F (Table 15.1-40). Chinook salmon were also observed in Tributaries UT 1.190 and UT 1.410 (Appendix 15.1B).

Chinook salmon fry generally emerge in the spring and remain in the freshwater rearing habitat until outmigration (Appendix 15.1A). While juveniles in some populations outmigrate as young-of-the-year fry, this life history pattern is thought to be uncommon in the Bristol Bay basin. Based on length frequency distributions, three age-classes of juvenile Chinook salmon have been observed in the UT: young-of-the-year subyearlings (0+), yearlings (1+), and 2+ age juveniles. The mean lengths of juvenile Chinook salmon by age-class based on fish measurements from the UT are shown on Figure 15.1-81. However, the proportion of juvenile Chinook salmon outmigrating at any age-class is unknown. Observations during the winter surveys documented juvenile Chinook salmon in UT-C, UT-D, and UT-E in the late fall prior to ice-up, and again in the following April (Appendix 15.1B), suggesting these reaches may provide overwintering habitat for rearing fish.

Based on field surveys, the relative abundance of juvenile Chinook salmon is shown for selected reaches on Figure 15.1-82. Juvenile Chinook salmon were the most abundant salmonids observed in UT-C, UT-D, and UT-E, with estimates as high as 320, 430, and 90 fish per 328 feet (100 meters), respectively. The abundance of juvenile Chinook salmon declined in UT-F to 13 fish per 328 feet (100 meters).

Juvenile Chinook salmon were predominantly found in mainstem channel habitats (run/glide, pool, and riffle) with the greatest observed densities occurring in run/glide habitat in UT-C (approximately 2 to 20 fish per 1,076 sf [100 m^2]; Figure 15.1-83). In other mainstem habitats, juvenile densities ranged from less than 1 to 9 fish per 1,076 sf (100 m^2) in riffles and were less than 3 fish per 1,076 sf (100 m^2) in pool habitat. Densities of juvenile Chinook salmon were considerably less in off-channel habitats, where the greatest observed density was 0.25 fish per 1,076 sf (100 m^2; Figure 15.1-77). Densities in tributaries were also low, with less than 0.05 fish per 1,076 sf (100 m^2; Appendix 15.1B, Table B.17-8).

Aerial surveys for adult Chinook salmon in the UT were conducted in 2004 through 2008. During this 5-year period, adult Chinook salmon entered the UT to spawn as early as July 6 and were present as late as September 17 (Figure 15.1-84). This run timing is protracted compared to the Chinook salmon spawning runs in the NFK and SFK, which started in early July and finished by August 29 and August 23, respectively. Adult counts peaked between July 31 and August 8.

During the course of the study, adult Chinook salmon mean index counts in the UT were greatest in 2004, with a mean index count of 178 salmon (Figure 15.1-84; Figure 15.1-85). The mean index count declined sharply in 2005 and remained relatively stable thereafter through 2008. Similar trends in Chinook salmon runs were also observed in the NFK and SFK watersheds and in the larger, encompassing Nushagak District, although the timing of the decline has been variable across years (Morstad et al. Table 15.1-15). Chinook salmon total run size for the Naknek-Kvichak District and escapement estimates into the Kvichak River were not available. However, it is worth noting that catch statistics for Naknek-Kvichak District Chinook salmon remained relatively stable from 2004 through 2008 (Morstad et al., 2010; Table 15.1-41).

Reach-specific counts allow for an assessment of the salmon spawner distribution within the UT watershed. Chinook salmon spawning has been documented in UT-A through UT-F (Figure 15.1-86), as well as in Tributaries UT 1.190 and UT 1.410 (Appendix 15.1B). The overall numbers of spawning adults in the UT in 2008 were low, ranging from five spawning adult observations in UT-F to 55 observations in UT-E (Table 15.1-42). UT-E and UT-C had the greatest mean survey counts of 14 and 13 spawning adults, respectively. Mean survey counts in UT-A, UT-B, UT-D, and UT-F ranged from three to five adults. Although the relative spawning abundance of Chinook salmon in the UT reaches is low, the UT Chinook salmon are more widely distributed than in either the NFK or SFK. The preponderance of springs and seeps throughout the mainstem UT (Chapter 7, Section 7.2) may facilitate access to upper stream reaches during low flow periods when adult Chinook salmon migrate upstream to spawn.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the UT with respect to the Naknek-Kvichak District and the greater Bristol Bay fishery. The Naknek-Kvichak District is one of five fishery districts within Bristol Bay. Chinook salmon within this district, which is comprised of the Kvichak, Alagnak, and Naknek rivers, have contributed approximately 5 percent of the total Bristol Bay Chinook salmon catch based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). Naknek-Kvichak District run estimates and Kvichak River escapement estimates for Chinook salmon were not available. However, commercial catch for Chinook salmon in the Naknek-Kvichak District from 2004 through 2008 ranged from 1,344 fish in 2008 to a high of 2,333 fish in 2006, with a 5-year average of 1,580 (Morstad et al., 2010; Table 15.1-41). Although not directly comparable, the UT Chinook salmon mean index counts (used as an index of escapement) ranged from 28 in 2008 to 178 in 2004 and averaged 76 for the 5-year study period.

Chum Salmon. Like Chinook salmon, the distribution of chum salmon in UT extends from UT-A to UT-F (Table 15.1-40). This documented distribution is largely comprised of adult chum salmon observations made during the aerial surveys conducted during the study period. Aside from the aerial surveys, only three adults and one juvenile chum salmon were observed during snorkel surveys conducted in the UT (Appendix 15.1B). The adult observations occurred in UT-C (August 2004), UT-E (July 2007), and UT-F (July 2008), and the one juvenile was observed in UT-D (July 2007).

The relative abundance of juvenile and adult chum salmon is shown for selected UT reaches on Figure 15.1-82. Chum salmon were the least abundant salmonid species shown throughout the UT, with all estimates less than 1 fish per 328 feet (100 meters). Due to the limited number of juvenile chum salmon observations, data were insufficient to evaluate juvenile length-frequency distributions, life history traits, and habitat associations (fish density) for this species. Juvenile chum salmon tend to have a rather brief period of stream residence prior to outmigration (Appendix 15.1A). It is therefore likely that the only

juvenile age-class for chum salmon in the UT is young-of-the-year, as was the case with chum salmon in the NFK and SFK.

Aerial surveys for adult chum salmon in the UT were conducted annually from 2004 through 2008. No adult chum salmon were observed during the 2004 aerial surveys and only three adults were observed in 2005 (July 24). Adults were observed in a minimum of two surveys in all other study years (Figure 15.1-87). In 2006 through 2008, adult chum salmon entered the UT to spawn as early as July 15 and were present as late as August 24. Peak adult counts occurred between July 31 and August 3.

Chum salmon are the least abundant of the four Pacific salmon species consistently found in the UT. Mean index counts for 2006 through 2008 were low, ranging between five and 17 adult chum salmon (Figure 15.1-88; Table 15.1-41). Despite these low counts, there appeared to be an overall increasing trend in chum salmon mean index counts in the UT from 2006 through 2008 (Figure 15.1-87; Figure 15.1-88). While this trend is similar to that observed for chum salmon in the NFK, the overall numbers of chum salmon in the NFK were much greater than in the UT. For comparison, the greatest mean index count in the NFK was 532 salmon (Table 15.1-15). Chum salmon total run for Naknek-Kvichak District and escapement estimates into the Kvichak River were not available ; however, chum salmon catch statistics for the Naknek-Kvichak District also showed an increasing trend, particularly from 2004 through 2006 (Morstad et al., 2010; Table 15.1-41).

Reach-specific counts allow for an assessment of the salmon spawner distribution within the UT. As with Chinook salmon, chum salmon spawning has been documented in UT-A through UT-F (Table 15.1-40), and the overall numbers of spawning adults in the UT in 2008 were low (Table 15.1-42). Total spawning chum salmon observations ranged from five observations in both UT-B and UT-C to 25 observations in UT-D. Across all UT reaches, the mean survey counts of spawning chum salmon in 2008 were consistently low (Figure 15.1-86). The maximum mean count of nine spawning fish occurred in UT-F, and the lowest mean count of two spawning fish occurred in UT-B (Table 15.1-42). The even distribution of spawning chum salmon throughout the UT is likely a result of the substantial groundwater inflow documented in the middle and upper reaches of the watershed (Chapter 7, Section 7.2), which may facilitate access to headwater reaches for upstream migrating adults as well as provide suitable spawning conditions. Furthermore, the relatively small body size of chum salmon typically enables chum salmon to access upstream reaches with low flows.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the UT with respect to the Naknek-Kvichak District and the greater Bristol Bay fishery. Chum salmon within the Naknek-Kvichak District, which is comprised of the Kvichak, Alagnak, and Naknek rivers, contributed approximately 20 percent of the total Bristol Bay catch based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). Naknek-Kvichak District run estimates and Kvichak River escapement estimates for chum salmon were not available. However, commercial catch for chum salmon in this district from 2004 through 2008 ranged from 29,972 fish in 2004 to a high of 457,855 fish in 2006, with a 5-year average of 262,758 (Morstad et al., 2010; Table 15.1-41). Although not directly comparable, the UT chum salmon mean index counts (used as an index of escapement) ranged from five in 2007 to 17 in 2008 and averaged 12 for the 3 years of the study period for which mean index counts were calculated.

Coho salmon. Coho salmon were the second-most abundant anadromous salmonid observed in the UT during the study period (Table 15.1-41). Both juveniles and adults were found in all UT reaches, from

UT-A to UT-G, and were the only anadromous salmonid observed in UT-G (Table 15.1-40). Coho salmon juveniles were present in the UT watershed year-round (Appendix 15.1B).

In general, coho salmon incubation and early fry development stages occur from the time of spawning through the winter months, with fry emerging in the spring (Appendix 15.1A). Based on length frequency distributions, four age-classes of coho salmon juveniles have been observed in UT: subyearling (0+), yearling (1+), 2+age, and 3+age fish (Bailey, 2009). Mean lengths for each age-class are shown on Figure 15.1-81. In many river systems throughout its range, coho salmon outmigrate as 1+ age, yearling fish, with some juveniles residing for up to 2 years in freshwater (Appendix 15.1A). However, the proportion of juvenile coho salmon outmigrating in the UT at any age-class is unknown. Juvenile coho salmon have been documented in UT as early as April and as late as November (Appendix 15.1B, Tables B.15-2, B.16-6, and B.17-7.). Observations during winter surveys indicated coho salmon were present in UT-D through UT-F in November, and again the following April, suggesting these reaches may provide overwintering habitat.

The relative abundance of juvenile and adult coho salmon in the UT is shown for selected reaches on Figure 15.1-82. Throughout the watershed, coho salmon abundance was the highest of fishes in most reaches—with the exception of UT-G, where sculpin were more abundant, and UT-C, where arctic grayling were more abundant. Abundance estimates for coho salmon ranged from a low of approximately 1 fish per 328 feet (100 meters) in UT-D beaver ponds to greater than 1,700 fish per 328 feet (100 meters) in UT-D pool habitat.

Coho salmon were found in mainstem channel, off-channel, and side channel habitats. Among the mainstem channel habitats, juvenile coho salmon densities were greatest in run/glide habitats; densities ranged from approximately 15 to 210 fish per 1,076 sf (100 m^2; Figure 15.1-83). Among the other mainstem channel habitats, densities ranged from approximately 15 to 65 fish per 1,076 sf (100 m^2) in riffles and from approximately 10 to 80 fish per 1,076 sf (100 m^2) in pool habitats. Juvenile coho salmon densities were similar within mainstem channels and side channels at 42 and 52 fish per 1,076 sf (100 m^2), respectively (Appendix 15.1B, Figure B.16-11). Overall, the density within off-channel habitats in the UT was lower (approximately 12 fish per 1,076 sf [100 m^2]). However, densities among various off-channel habitat types were similar to those observed in the mainstem channel (Figure 15.1-77); coho salmon densities in off-channel habitats ranged from approximately 2 fish per 1,076 sf (100 m^2) in isolated pools to approximately 60 fish per 1,076 sf (100 m^2) in percolation channels. Juvenile coho salmon were also commonly found in tributaries in the UT watershed (Appendix 15.1B, Tables B.17-8 and B.18-8). Juvenile densities in tributaries were greater than 100 fish per 1,076 sf (100 m^2) in several habitat types, including pools, backwaters, and run/glides. The greatest observed juvenile density was approximately 800 fish per 1,076 sf (100 m^2) in backwater habitat in Tributary UT 1.410 (Appendix 15.1B, Table B.17-8).

Aerial surveys for adult coho salmon in the UT were conducted from 2004 through 2008. Adult coho salmon entered the UT to spawn as early as August 8 and were present as late as November 16 (Figure 15.1-89). Adult peak counts occurred between September 2 and September 5.

Over the study period, the mean index counts for coho salmon remained relatively stable (1,143 to 1,773 salmon) in the UT, although an increase in the mean index count was observed from 2004 to 2006 (Figure 15.1-90). The coho salmon mean index counts in the UT were considerably greater than those in the NFK and SFK, which ranged from 43 to 494 during the 5-year study period (Table 15.1-15). Coho salmon total

run for Naknek-Kvichak District and escapement estimates to the Kvichak River were not available; however, coho salmon catch statistics for the Naknek-Kvichak District remained relatively stable from 2004 through 2008 (Morstad et al., 2010; Table 15.1-41).

In 2008, aerial surveys conducted in the UT indicated that Tributary UT 1.60 supported proportionally large runs of both coho and sockeye salmon. A separate mean index count for UT 1.60 allowed for a direct comparison between the spawning runs in this tributary and the UT watershed as a whole. For coho salmon, the overall timing of the UT 1.60 spawning run was shorter and the run size smaller than that observed in the UT mainstem survey area (Figure 15.1-91). In addition, the UT 1.60 run peaked approximately 10 days later than the mainstem run. The mean index counts for coho salmon were 332 in UT 1.60 and 1,598 in the mainstem index area (Figure 15.1-92). In 2008, Tributary UT 1.60 supported approximately 17 percent of the total coho salmon run in the UT watershed.

Reach-specific counts allow for an assessment of the salmon spawner distribution within the watershed. Coho salmon spawning was documented in all mainstem UT reaches, as well as in Tributaries UT 1.60, UT 1.350, UT 1.350.60, UT 1.390, and UT 1.410 (Appendix 15.1B). Analysis of the relative abundance and distribution of spawning coho salmon among the UT reaches in 2008 revealed a greater number of spawning coho in UT-E than in the other reaches (Table 15.1-42; Figure 15.1-86). The mean number of spawners observed in UT-E was 293 fish. UT-D and UT-F also had relatively high numbers of spawning fish, with means of 188 and 185 fish, respectively. The three lowest reaches (UT-A through UT-C) had moderate numbers of spawning fish, with means ranging from 45 fish in UT-C to 99 fish in UT-A. Only six total spawning adults were observed in UT-G. Similar to the NFK and SFK, the wide distribution of coho salmon in the UT may be a function of the late coho salmon migration period coinciding with increased stream flows (Figure 15.1-68). High stream flows can facilitate upstream movements and access to upstream reaches.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the UT with respect to the Naknek-Kvichak District and the greater Bristol Bay fishery. Coho salmon within the Naknek-Kvichak District, which is comprised of the Kvichak, Alagnak, and Naknek rivers, contributed approximately 6 percent of the total Bristol Bay catch based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). Naknek-Kvichak District run estimates and Kvichak River escapement estimates for coho salmon were not available. However, commercial catch for coho salmon in this district from 2004 through 2008 ranged from 2,142 fish in 2004 to a high of 7,059 fish in 2008, with a 5-year average of 3,972 (Morstad et al., 2010; Table 15.1-41). Although not directly comparable, the UT coho salmon mean index counts (used as an index of escapement) ranged from 1,143 in 2004 to 4,363 in 2006 and averaged 2,219 for the 5-year study period.

Sockeye Salmon. The distribution of sockeye salmon in the UT extended from UT-A to UT-F (Table 15.1-40). Both juveniles and adults were found in all six of these UT reaches. While sockeye salmon was the most abundant adult anadromous salmonid observed in the UT during the study period, juvenile sockeye salmon were observed less frequently than coho and Chinook salmon juveniles (Appendix 15.1B, Tables B.12-7, B.13-7, B.14-6, B.15-2, B.16-6, B.17-7, and B.18-7). This observation is likely a reflection of juvenile sockeye salmon moving downstream and/or into lake rearing habitats within 2 to 3 weeks of emergence (Appendix 15.1A).

Sockeye salmon incubation and early fry development stages occur from the time of spawning through the winter months, with fry emerging in the early spring (April and May; Figure 15.1-19). Emergence

typically occurs either under the ice or within groundwater influenced ice-free areas (Appendix 15.1A). Length frequency data indicate that two age-classes of sockeye salmon juveniles occur in the UT: young-of-the-year (0+ age) and yearling (1+ age). Mean lengths for each age-class are shown on Figure 15.1-81. The proportion of juvenile sockeye salmon outmigrating at any age class is unknown for the UT. Juvenile sockeye salmon were observed during fish surveys in April and in June through September.

The relative abundance of juvenile sockeye salmon is shown for selected reaches on Figure 15.1-82. Ranging from a low of approximately 1 to 8 fish per 328 feet (100 meters) in UT-F to a high of approximately 5 to 35 fish per 328 feet (100 meters) in UT-E, sockeye salmon juveniles were less abundant than coho salmon and, in most cases, Chinook salmon. This result reflects the absence of juvenile sockeye salmon during fish surveys due to their abbreviated riverine residence time.

Sockeye salmon densities in the mainstem UT habitats, including run/glides, riffles, and pools, were consistently low, at less than 3 fish per 1,076 sf (100 m^2; Figure 15.1-83). Densities in the off-channel habitats were also considerably low (less than 2 fish per 1,076 sf [100 m^2]; Figure 15.1-77). The greatest observed density of juvenile sockeye salmon (approximately 5 fish per 1,076 sf [100 m^2]) was in pool habitat within Tributary UT 1.390 (Appendix 15.1B, Table B.17-8).

Aerial surveys for adult sockeye salmon in the UT were conducted from 2004 through 2008. During the study period, adult sockeye salmon entered the UT to spawn as early as July 6 and were present as late as October 2 (Figure 15.1-93). The timing of annual peak counts ranged from July 17 to August 3.

The mean index count analysis suggests a decreasing trend in the UT sockeye salmon spawning runs from 2004 through 2007 and then increasing through 2008 (Figure 15.1-93; Figure 15.1-94). The greatest mean index count during the baseline period occurred in 2004, when a mean of 31,088 fish was observed (Table 15.1-41). In comparison, the 2008 mean index count was 11,120 salmon. Adult sockeye salmon mean index counts from 2004 through 2008 have generally been one to two orders of magnitude greater in the UT than in the NFK and SFK (Table 15.1-15). The exception was observed in 2006 and 2007, when mean index counts in the UT dropped below 5,000 fish (Table 15.1-41). During the study period, sockeye salmon escapement in the Kvichak River also peaked in 2004 and dropped by more than 50 percent in 2005 (Baker et al., 2009). For the entire Naknek-Kvichak District, the total run remained relatively stable over this 5-year period, ranging from approximately 13.9 to 17.8 million sockeye salmon (Morstad et al., 2010; Table 15.1-41).

In 2008, aerial surveys were conducted for Tributary UT 1.60 and indicated that UT 1.60 supported proportionally large runs of both coho and sockeye salmon. A separate mean index count for UT 1.60 allowed for a direct comparison between the spawning runs in this tributary and the UT watershed as a whole. For sockeye salmon, peak index counts for both UT 1.60 and the UT mainstem survey area occurred on August 3 (Figure 15.1-95). However, the overall timing of the UT 1.60 spawning run was shorter and the run size smaller than that observed in the UT mainstem survey area. The mean index counts for sockeye salmon were 8,308 in UT 1.60 and 11,120 in the mainstem index area (Figure 15.1-96). In 2008, Tributary UT 1.60 supported approximately 43 percent of the total sockeye salmon run in the UT watershed.

Reach-specific counts allow for an assessment of the salmon spawner distribution within a watershed. Sockeye salmon were observed spawning in UT-A through UT-F, as well as in Tributaries UT 1.60, UT 1.190, UT 1.350.20, UT 1.390, and UT 1.410 (Appendix 15.1B). Analysis of the relative abundance and

distribution of spawning sockeye salmon among the UT reaches in 2008 revealed that the greatest numbers of spawning sockeye salmon occurred in UT-A (Table 15.1-43; Figure 15.1-97). The total number of sockeye salmon spawning observations in UT-A (including Tributary UT 1.60) in 2008 was 103,233 adults. These observations were made over a total of 10 surveys; therefore, the mean survey count of spawning fish in UT-A is 10,323 adults. Upstream of UT-A, the number of spawning sockeye salmon within each UT reach progressively decreased, from a mean survey count of 4,608 in UT-B to a mean of 47 in UT-F.

Mean index counts were used to provide a perspective of the relative size of salmon runs in the UT with respect to the Naknek-Kvichak District and the greater Bristol Bay fishery. Sockeye salmon within the Naknek-Kvichak District, which is comprised of the Kvichak, Alagnak, and Naknek rivers, contribute approximately 33 percent of the total Bristol Bay catch based on the 20-year average from 1989 to 1998 (Morstad et al., 2010). Total inshore run estimates (commercial catch and escapement) provided by ADF&G for the Naknek-Kvichak District sockeye salmon from 2004 through 2008 ranged from a low of 13,945,960 fish in 2006 to a high of 17,792,948 fish in 2008, with a 5-year average of 16,006,818 (Morstad et al., 2010; Table 15.1-41). During the same time period, Kvichak River sockeye salmon escapement estimates ranged from approximately 2.3 million in 2005 to 5.5 million in 2004 and had a 5-year average of approximately 3.3 million (Baker et al., 2009; Table 15.1-41). In contrast, the UT sockeye salmon mean index counts (used as an index of escapement) ranged from 2,362 in 2007 to 31,088 in 2004 and averaged 11,841 for the 5-year study period.

Pink Salmon. Adult pink salmon (*O. gorbuscha)* were documented in the UT during aerial spawning surveys in 2006 and 2007. Three hundred thirty-six pink salmon were observed on two dates in 2006: 315 on July 31 and 21 on September 4. In 2007, only three pink salmon were observed: one on July 26 and two on August 10. All observations occurred in the lower half of the UT. No juvenile pink salmon were observed during the study period. Pink salmon are known to spawn in odd and even year cohorts within a river basin (Appendix 15.1A). Thus, it was anticipated that a small run of pink salmon would occur during 2008 surveys. However, no adult pink salmon were observed in the UT in 2008. It is uncertain whether the pink salmon observed in 2006 and 2007 constitute a sustainable run into UT or whether the fish were strays from another system. The UT was the only watershed in the mine study area where pink salmon were observed during the 2004 through 2008 environmental baseline fish resource studies.

UT Non-anadromous (Resident) Salmonid Fishes

Non-anadromous salmonid fishes found in the UT watershed include arctic grayling, Dolly Varden, rainbow trout, and whitefish species (Table 15.1-43). Although these species were less abundant than anadromous salmonids, they represent an important component of the fish community in this watershed and support local and regional sport and subsistence fisheries. Rainbow trout are particularly important with respect to recreational fisheries for resident salmonids. The catch rate for rainbow trout in the Kvichak River drainage averaged 21,219 fish per year from 2000 to 2004 (Dye et al., 2006). Fall et al. (2006) reported between 55 and 92 percent of the households in the towns of Iliamna, Newhalen, and Nondalton gathered resident salmonid fishes for subsistence use, depending upon the species (Table 15.1-18).

The distribution, life history, relative abundance, and habitat associations of each of the four non-anadromous salmonid taxa present in the UT are discussed in the following sections. The mean length of non-anadromous salmonids by age class captured in the UT is shown on Figure 15.1-98.

Arctic Grayling. Arctic grayling were found in all reaches of the UT, with the exception of the headwater reach (UT-G; Table 15.1-43). Both adult and juvenile fish were observed in UT-A through UT-F.

Relatively little is known about the life history of arctic grayling in the UT. Elsewhere in their range, adults overwinter in lakes or mainstem channels and migrate to upstream tributaries to spawn in May and June (see Appendix 15.1A). In the UT, both adults and juveniles have been observed from May through October (Appendix 15.1B, Tables B.15-2 and B.17-7). The mean length of arctic grayling by age class that were captured in UT is presented on Figure 15.1-98.

The relative abundance of juvenile and adult arctic grayling is shown for selected reaches on Figure 15.1-82. Unlike the SFK, where arctic grayling abundance was markedly higher in the headwater reaches, the abundance of this species in the UT was greatest in the middle reach. The highest recorded abundance for juvenile arctic grayling was in UT-C at 2,600 fish per 328 feet (100 meters). Abundance of grayling in the reaches upstream and downstream of UT-C were substantially lower, ranging from less than 1 fish per 328 feet (100 meters) to 25 fish per 328 feet (100 meters).

Fish-habitat associations, based on data from UT-C, UT-E, and UT-F, indicated that arctic grayling used habitats within mainstem channel, side channel, and off-channel habitats. Fish densities were consistently highest in run/glide habitats, with densities up to approximately 160 fish per 1,076 sf (100 m^2; Figure 15.1-83). Densities in riffles ranged from less than 1 to approximately 3 fish per 1,076 sf (100 m^2) and were approximately 2 fish per 1,076 sf (100 m^2) in pool habitat. Arctic grayling were inconsistently found in off-channel habitat types (Figure 15.1-99), but were primarily located in percolation channels at a density of 5.5 fish per 1,076 sf (100 m^2) and in beaver ponds at a density of 0.05 fish per 1,076 sf (100 m^2).

Dolly Varden. Like arctic grayling, Dolly Varden were widely distributed throughout the UT (Table 15.1-43), although none were documented in UT-A. Both adult and juvenile fish were observed from UT-B upstream into UT-G.

Both anadromous and non-anadromous populations of Dolly Varden are thought to occur in Bristol Bay drainages (Appendix 15.1A). However, little is known about the life history pattern(s) they exhibit in the UT. Adults have been observed from June through October and juveniles from April through November in UT (Appendix 15.1B Tables B.14-6, B.15-2, B.16-6, B.17-7, and B.18-7). In addition, juvenile Dolly Varden have been documented in November and April of the following year in UT-C through UT-G, indicating they overwinter in UT.

The relative abundance of juvenile and adult Dolly Varden is shown for selected reaches on Figure 15.1-82. Dolly Varden abundances were generally low relative to other species, with estimates ranging from less than 1 to approximately 8 fish per 328 feet (100 meters) from UT-C upstream through UT-G. Abundance estimates in tributaries within these reaches were higher, ranging from approximately 8 to 38 fish per 328 feet (100 meters; Appendix 15.1B, Figures B.14-8b, B.17-8b, and B.18-8b).

Dolly Varden densities were generally low across all mainstem habitat types (Figure 15.1-83). Habitat-specific densities of Dolly Varden were less than 1 fish per 1,076 sf (100 m^2) in pool, riffle, and run/glide habitats in reaches UT-C, UT-E, and UT-F. Slightly greater densities, ranging from approximately 2 to 3 fish per 1,076 sf (100 m^2), were documented in UT-G. In tributaries, Dolly Varden densities ranged from

approximately 2 to 10 fish per 1,076 sf (100 m^2) and were generally greatest in pool and cascade habitat (Appendix 15.1B, Figures B.17-9b and B.18-9b). Dolly Varden were not frequently encountered in off-channel habitats (Figure 15.1-99). They were recorded only within beaver ponds at low densities of 0.2 fish per 1,076 sf (100 m^2).

Rainbow Trout. Similar to coho salmon, arctic grayling, and Dolly Varden, rainbow trout were widely distributed throughout the UT. However, they were not documented in the uppermost headwater reach, (UT-G; Table 15.1-43). Both adult and juvenile rainbow trout have been documented in UT-A through UT-D, and in UT-F. Only juvenile trout were documented in UT-E.

An adfluvial rainbow trout population exists in Iliamna Lake and its tributaries, including the UT. This population has been the subject of a radio telemetry study monitoring the movements and site fidelity of adult rainbow trout in the UT. Adult trout move from their overwintering areas at the mouths of several northwest Iliamna Lake tributaries into the lake and then into the UT to spawn after ice-out, from mid-May through June. An additional migration of large, adult trout foraging in the UT was documented in late summer. These fish move into the UT with spawning sockeye salmon and subsequently leave to return to Iliamna Lake. Ninety-five adfluvial rainbow trout from UT-A and two trout from UT-C were collected and radio tagged during the study. From May through October, one hundred seventy-seven additional rainbow trout adults were also observed throughout the UT (Appendix 15.1B, Tables B.12-7, B.13-7, B.14-6, B.15-2, and B.17-7). Based on size distributions, these adults represent a mix of post-spawning adfluvial fish and a resident population of rainbow trout.

Juvenile rainbow trout were also observed during most months (April through November) in the UT. Based on the scientific literature, stream residence time for juvenile adfluvial fish can be brief or last up to 3 years depending upon the watershed (Appendix 15.1A). Thus, the proportion of juvenile fish contributing to the resident and adfluvial rainbow trout populations with the UT is currently unknown.

The relative abundance of juvenile and adult rainbow trout is shown for reaches with available abundance data on Figure 15.1-82. Aside from chum salmon, rainbow trout abundance was generally the lowest of the salmonid species, with abundance estimates of less than 1 to 20 fish per 328 feet (100 meters). One exception was in UT-D, where rainbow trout abundance was as high as approximately 240 fish per 328 feet (100 meters).

Rainbow trout were found in low densities in multiple habitats in mainstem channel and off-channel habitats. In the mainstem UT, rainbow trout were found in both fast and slow water habitat types, including riffles, run/glides, and pools, at densities of less than 1 fish per 1,076 sf (100 m^2; Figure 15.1-83). Among off-channel habitats, rainbow trout were observed only in beaver ponds (0.08 fish per 1,076 sf [100 m^2]; Figure 15.1-99).

Whitefish. In the UT, the whitefish species assemblage was documented in UT-A, UT-C, and UT-D (Table 15.1-43). Adult whitefish were observed in each of these three reaches, whereas juveniles were only found in UT-D. In many cases, these fish were observed during snorkel surveys and could not be successfully identified to species. While round whitefish were documented in the NFK, other species of whitefish have been reported in the Bristol Bay drainage, including least cisco (McPhail and Lindsey, 1970) and humpback whitefish (Woody and Young, 2007). Thus, any of these species of whitefish could be found in UT reaches. Within the UT watershed, whitefish were found only in the mainstem channel. Abundance estimates ranged from 0.24 to 1.35 fish per 328 feet (100 meters; Figure 15.1-82), and

densities in pools, run/glides, and riffles were consistently less than 1 fish per 1,076 sf (100 m^2; Figure 15.1-83).

UT Non-Salmonid Fishes

Non-salmonid fishes found in the UT watershed include sculpin and stickleback species (Table 15.1-44). Information regarding the distribution, relative abundance, and habitat associations of these two non-salmonid species groups in the UT is provided below.

Sculpin. Sculpin have been documented in all mainstem reaches of the UT, making the cottids among the most widely distributed fish taxa in the watershed (Table 15.1-44). Both juvenile and adult sculpin have been documented in every UT reach except UT-B, where only the juvenile life stages were observed. Although sculpin were not identified to species, both slimy sculpin and coastrange sculpin are known to inhabit the Bristol Bay basin (Appendix 15.1A). Slimy sculpin were documented in the UT by Buell (1994).

Sculpin were the most abundant resident fishes throughout the mainstem UT, with abundance estimates ranging from 13 to 258 fish per 328 feet (100 meters) of stream (Figure 15.1-82). Sculpin were also found in off-channel and side channel habitats in UT-D, although they were less abundant in these habitats than in the mainstem channel (less than 1 fish per 328 feet [100 meters]; Appendix 15.1B, Figure B.15-8). Sculpin densities were variable among the mainstem riffle, run/glide, and pool habitats (Figure 15.1-83), but the greatest observed density of approximately 40 fish per 1,076 sf (100 m^2) was in run/glide habitat within UT-G. The greatest density in the UT tributaries was in UT-G, where 27 fish per 1,076 sf (100 m^2) were documented in pool habitat (Appendix 15.1B, Figure B.18-9b). Among the off-channel habitats, beaver ponds supported the greatest density of sculpin (approximately 3 fish per 1,076 sf (100 m^2; Figure 15.1-99).

Stickleback. Stickleback were documented in UT-A through UT-F in both fast and slow water habitats (Table 15.1-44). Observations included juvenile and adult life history stages, and both ninespine stickleback and threespine stickleback were found.

Stickleback abundance was generally low in most mainstem reaches, with less than 7 fish per 328 feet (100 meters) recorded (Figure 15.1-82). However, an abundance of 25 fish per 328 feet (100 meters) was documented in UT-D. Stickleback were also abundant in off-channel and side channel habitats; relative abundance estimates in UT-D and UT-E off-channel and side channel habitat ranged from approximately 4 to 50 fish per 328 feet (100 meters; Appendix 15.1B, Figures B.15-8 and B.16-10).

Stickleback densities were approximately 1 fish per 1,076 sf (100 m^2) or less in most habitat types (Figure 15.1-83). Stickleback densities in UT tributaries were similarly low (less than 0.2 fish per 1,076 sf [100 m^2] in run/glide and riffle habitats; Appendix 15.1B, Figure B.17-9b). However, among off-channel habitats in the UT, stickleback were the most dominant species found in isolated pools, beaver pond outlet channels, and beaver ponds, where densities were between 4 and 11 fish per 1,076 sf (100 m^2; Figure 15.1-99).

UT Watershed Synthesis

Four anadromous salmon species (Chinook, chum, coho, and sockeye salmon) spawned annually in habitats throughout the mainstem UT. Chinook and chum salmon were documented spawning from the beginning of UT-A, upstream to approximately 37 RM (59 RK) in UT-F. Sockeye and coho salmon were documented spawning from the lowest to highest reaches in the watershed. In addition, what appeared to be exploratory runs of pink salmon were documented in the UT in 2006 and 2007.

Based on the 2008 spawning abundance and distribution analysis, the greatest abundance of sockeye salmon spawners was found in the lowest reach (UT-A), with spawner abundance declining in numbers in each consecutive upstream reach continuing into the headwater reach (UT-G). In contrast, the greatest abundance of coho spawners were in middle and uppermost reaches (UT-D, UT-E, and UT-F). The instream-flow model predictions, which are based on relationships between substrate sizes, water velocities, and species preferences for these criteria, help to explain the pattern for coho salmon, because the greatest amount of available coho salmon spawning habitat was predicted in the middle reaches. However, results for sockeye salmon habitat availability do not explain the sockeye salmon distribution. It is possible the lack of prediction capability for sockeye salmon is related to a limited number of instream flow transects located within UT-A and UT-B, the reaches with the highest abundances of sockeye spawning.

It is interesting to note that, unlike the NFK and SFK, a direct relationship between spawning distributions of sockeye and chum salmon and groundwater inflow areas was not apparent in the UT. The UT generally has more stable flows, with no ephemeral areas and numerous seeps and springs contributing to river flow. The thermal regime in the UT also was distinct from the NFK and SFK, with slightly cooler temperatures. In typical fashion, water temperatures in the UT generally increase as the river flows downstream. This thermal difference in the UT compared to the SFK and NFK is likely attributed to the prominent groundwater influence in the middle and upper watershed, cold water input from Tributary UT 1.190, and a North/South alignment in the upper river that provides shade from the surrounding terrain and helps to insulate water temperature.

Five tributaries in the UT support spawning populations of anadromous salmonids. Most tributaries support small numbers of spawning sockeye and coho salmon. Large spawning populations were observed in UT 1.60, which is located low in the watershed—draining into the upstream end of UT-A. Aerial survey data indicate this creek may support as much as 43 percent of the watershed total for adult sockeye salmon and 17 percent of the total for coho salmon. The Tributary UT 1.60 and UT 1.350 subwatersheds also support a life history variation for coho and sockeye salmon. Small populations of lake-spawning sockeye and coho salmon were documented spawning in several small lakes and ponds within these subwatersheds.

A comparison of mean adult salmon index counts among watersheds shows that the UT sockeye salmon run was the largest run within the study area. The mean index counts for UT coho salmon were larger by one or two orders of magnitude than those in the NFK and SFK. In contrast, the runs of UT Chinook and chum salmon were generally an order of magnitude lower compared to the other two watersheds.

The overall distribution of river-rearing juvenile Pacific salmon in the UT was driven largely by juvenile coho salmon, with peaks in abundance in the middle to upper UT, including UT-C through UT-F. The highest abundance estimates for Chinook salmon in the UT also were located in the middle watershed.

Limited numbers of juvenile sockeye salmon were found up through UT-F in early summer, and they appear to rear in lower UT reaches throughout the summer. The only anadromous salmon documented in UT-G were coho salmon.

Juvenile Chinook salmon were predominantly found in mainstem channel, fast water habitats that are present through the UT. Juvenile coho salmon were widely dispersed throughout the mainstem channel and tributaries and occupied a variety of habitat types. High relative abundance and densities of coho salmon were found in the mainstem channel glides and riffles, pools, beaver ponds, and tributary backwaters. This broad habitat use is consistent with the fact the coho salmon were the most abundant juvenile fishes in this watershed.

Patterns evident for sockeye salmon distribution in the UT were also noteworthy. Although sockeye salmon typically out migrate in their first spring after emergence, some juvenile sockeye were found in the upper reaches of the UT early into the summer rearing period and in lower reaches throughout the summer. These data indicate that some sockeye are rearing in the mainstem UT for several months.

At least seven non-anadromous salmonids and non-salmonid fishes were present in the UT. In general, these stream-dwelling fishes were distributed in low numbers throughout most of the watershed. Dolly Varden, sculpin, and one arctic grayling were the only resident fishes found in the headwater reach (UT-G). Arctic grayling and sculpin were the most widespread of the non-anadromous fishes and were documented in all reaches, as well as in several tributaries. The relative abundance of these fishes was generally low, with the exception of arctic grayling in UT-C, rainbow trout in UT-B, and sculpin in UT-C, UT-E, and UT-F.

Although some species-specific abundance patterns were evident, overall the freshwater fish assemblage in the UT was more consistent throughout the watershed and tributaries compared to the NFK and SFK assemblages. Large numbers of fish and similar species composition were documented from UT-B to UT-F. This distribution may be reflective of the overall stable habitat conditions in the UT. No ephemeral areas were documented and no warm water lakes are present in the UT. Furthermore, areas of groundwater inflow were widely dispersed throughout the middle and upper portions of the watershed and, thus, a more stable flow regime was present. The relatively constant fish assemblage among reaches in the UT is consistent with similar levels of habitat availability in UT-B through UT-F, as predicted by the instream-flow model.

15.1.6.4 Koktuli River Mainstem

KR Mainstem Overview

The KR is a moderate-sized drainage (Figure 15.1-100) of the Nushagak-Mulchatna system that ultimately flows into Bristol Bay. The Nushagak River drainage is one of eight river basins draining Southwest Alaska into Bristol Bay (Figure 15.1-5). The KR drainage within the mine study area comprises 218 mi^2 (565 km^2; 140,000 acres) or 1.7 percent of the Nushagak-Mulchatna River system and 0.6 percent of the entire Bristol Bay drainage basin (Table 15.1-2). The KR has an upper mainstem river length of approximately 29 miles (46 km) within the mine study area and an overall mainstem river length of 39 miles (62 km).

The KR originates at the confluence of the NFK and SFK, flowing northwesterly until it exits the fish resources study area at its confluence with the Swan River. The highest elevation in the KR drainage is Cone Mountain (elevation 2,760 feet [841 meters]; Chapter 4). The lowest elevation in the watershed within the mine study area is at the confluence with the Swan River at 580 feet (177 meters). The watershed is bounded by a series of low, isolated mountain blocks with Cone Mountain to the northeast. The surface water drainage divides are poorly defined.

The upper reach of the mainstem KR is more than 31 miles (50 km) downstream from the Pebble Deposit, therefore the study efforts in the KR were less intense than in the other three watersheds. Because the fish resources mine study area was limited to the upper KR mainstem, conditions related to non-fish resource areas (e.g., hydrology and water quality) are not described in this section. The information presented below is limited to the results of instream flow habitat and fish studies and applies only to the area sampled. Instream flow habitat surveys included four transects in spawning habitats (Table 15.1-10). Fish resource surveys in the KR have included: fish/habitat association studies in mainstem waters, fish distribution and relative abundance surveys, winter fish surveys, and adult salmon surveys (Table 15.1-1). Locations of these study sites are summarized on Figure 15.1-100. Other information and data pertaining to the KR are presented in: Chapter 7, Section 7.2 (hydrology); Chapter 9, Section 9.1 (water quality); Section 15.2 (invertebrates); Appendix 15.1C (instream flow); and Appendix 15.1D (water temperature).

KR Aquatic Habitat

KR Habitat/Flow Relationships

The habitat time series for the KR was computed for salmonid fish species in the mainstem KR reach (Photo 15.1-29). Four (4) transects corresponding to two transects in riffle and one each in run and island complex habitats were used in the analysis. Transect weighting in accordance with the frequency of representative habitat types in the reach is summarized in Table 15.1-10. The time series reflect the total habitat area for each day during the period a given species and life stage is present. Modeling results are presented for spawning and juvenile life stages of Chinook, chum, coho, and sockeye salmon, as well as for spawning, juvenile, and resident adult life stages of arctic grayling, Dolly Varden, and rainbow trout in Appendix 15.1C (Tables 70 through 72, and Figures 112 through 114). The total estimated amount of habitat expressed in acres, for each species available within a given reach based on the median daily flows over the respective time periods for each life stage is displayed in the appendix figures.

The results indicate a substantial variability in habitat amounts on a daily and monthly basis, in response to changes in flow. This variation is most evident during flow transitional periods. For example, during the spring-summer period when flows are declining there is a general increase in juvenile habitat. During the late summer-fall period, when flows increase, there is a general decrease in spawning habitat when river velocities become slightly higher than optimal for spawning for most of the salmonid species. Conversely, the spring spawning species, including arctic grayling and rainbow trout, show a strong decrease in available spawning area when river flow decreases in the late May and June time frame. The time series analysis represents a first step in evaluating how baseline flow conditions influence fish habitats in the KR temporally and spatially. Additional time series based on wet, dry, and average year conditions, as well as a series of associated habitat duration curves for the KR are provided in Appendix 15.1C.

KR Fish Resources/Assemblage

Based on sampling conducted between 2004 and 2008, the fish community inhabiting the upper KR mainstem consists of at least 10 different species (Table 15.1-45), including: four anadromous salmonid (Chinook, chum, coho, and sockeye salmon), four non-anadromous (resident) salmonid (arctic grayling, Dolly Varden, rainbow trout, and whitefish species), and two non-salmonid fishes (sculpin species and threespine stickleback). Off-channel habitats were not surveyed in the KR watershed, and thus, inferences about fish use of off-channel habitats in the KR watershed cannot be made. The species composition mix of anadromous and resident fish species in the KR is shown on Figure 15.1-100.

The life stage periodicity for anadromous and non-anadromous salmonids is presented on Figure 15.1-19. Figure 15.1-19 was developed based on a general understanding of local fish populations and refers to the general timing of fish life history stages for the entire aquatic resources study area (Appendix 15.1C). Life history information specific to the KR is included in the species descriptions below and general life histories are described in Appendix 15.1A.

KR Anadromous Salmonid Fishes

Anadromous salmonid fishes represent the most abundant fish taxa in the KR (Figure 15.1-100). The distribution, life history, spawning abundance, relative abundance, and habitat associations of each of the four species of anadromous salmonids present in the upper KR mainstem are discussed below.

Chinook Salmon. Chinook salmon have been documented in the upper KR mainstem (Table 15.1-46). Field surveys identified both juvenile and adult Chinook salmon in July and August (Appendix 15.1B, Table B.19-2). In addition to providing spawning, incubation, and rearing habitat, the upper KR mainstem is a migratory corridor for adult and juvenile Chinook salmon that use upstream habitats in the NFK and SFK watersheds.

Chum Salmon. Chum salmon have likewise been documented in the upper KR mainstem (Table 15.1-46), although field surveys only identified adults. These fish were observed in July and August (Appendix 15.1B, Table B.19-2). The abbreviated riverine residence time of juvenile chum salmon prior to downstream migration likely explains the absence of juvenile observations in the upper KR mainstem during summer surveys. In addition to providing spawning, incubation, and rearing habitat, the upper KR mainstem is a migratory corridor for adult and juvenile chum salmon that use upstream habitats in the NFK and SFK watersheds.

Coho Salmon. Coho salmon have been documented in the upper KR mainstem (Table 15.1-46), with adults found in July and juveniles in July and August (Appendix 15.1B, Table B.19-2). In addition to providing spawning, incubation, and/or rearing habitat, the upper KR mainstem is a migratory corridor for adult and juvenile coho salmon that use the NFK and SFK.

Sockeye Salmon. Sockeye salmon have been documented in the upper KR mainstem (Table 15.1-46). Field surveys identified juvenile and adult sockeye salmon in July and August (Appendix 15.1B, Table B.19-2). In addition to providing spawning, incubation, and rearing habitat, the upper KR mainstem is a migratory corridor for adult and juvenile sockeye salmon that use upstream habitats in the NFK and SFK watersheds.

ADF&G Commercial Fish Division sockeye salmon harvest and spawning escapement estimates since 1990 for the Nushagak Fish District have been summarized in Chapter 21 and by ADF&G (2006a). Harvest of fish destined for the Nushagak District appears to occur at a rate of 60 to 70 percent.

KR Non-anadromous (Resident) Salmonid Fishes

Although non-anadromous salmonid fishes are generally less abundant than anadromous salmonids in the upper KR mainstem, they represent an important component of the fish community in this watershed. The distribution, life history, relative abundance, and habitat associations of each of the four taxa of non-anadromous salmonids present in the upper KR mainstem are discussed in the following sections.

Arctic Grayling. Arctic grayling were documented in the upper KR mainstem (Table 15.1-46). Adults and juveniles were observed in July through September, and juveniles were recorded in July (Appendix 15.1B, Table B.19-2). Arctic grayling (8.1 fish per 328 feet [100 meters]) were more abundant than both Dolly Varden and rainbow trout. The relative abundance of arctic grayling could only be compared across two habitat types, pools (11 fish per 328 feet [100 meters]) and riffles (4.9 fish per 328 feet [100 meters]).

Dolly Varden. Both adult and juvenile Dolly Varden have been documented in the upper KR mainstem (Table 15.1-46). Field surveys identified adults and juveniles in July, but only juveniles in April and August (Appendix 15.1B, Table B.19-2). Dolly Varden (3.0 fish per 328 feet [100 meters]) were more abundant than rainbow trout, but less abundant than all other species recorded. In considering fish-habitat associations, the relative abundance of Dolly Varden could only be compared across two habitat types, riffles (5.6 fish per 328 feet [100 meters]) and pools (0.7 fish per 328 feet [100 meters]).

Rainbow Trout. Both adult and juvenile rainbow trout have been documented in the upper KR mainstem (Table 15.1-46). Field surveys identified adults in July and September. Juvenile trout were observed only during the month of July (Appendix 15.1B, Table B.19-2). Rainbow trout were the least abundant salmonid fish observed (2.0 fish per 328 feet [100 meters]) and were associated with both riffle (2.1 fish per 100 meter) and pool (2.0 fish per 100 meter or 328 ft) habitat types.

Whitefish. Adult whitefish were documented in the upper KR mainstem (Table 15.1-46) in July and August (Appendix 15.1B, Table B.19-2). These fish were observed during snorkel surveys and could not be identified to species. Round whitefish were documented upstream in the NFK watershed and other species of whitefish have been reported in the Bristol Bay drainage, including least cisco (McPhail and Lindsey, 1970) and humpback whitefish (Woody and Young, 2007). Thus, all of these species could be present in the KR.

KR Non-salmonid Fishes

The distribution, life history, relative abundance, and habitat associations of the two non-salmonids present in the upper KR mainstem are discussed in the following sections.

Sculpin. Sculpin have been documented in the upper KR mainstem (Table 15.1-46), although observations were limited to five individuals. Sculpin were seen in July and included one juvenile as well as four from an indeterminate life stage (Appendix 15.1B, Table B.19-2). Although sculpin were not identified to species, slimy sculpin are known to inhabit the Bristol Bay basin (Appendix 15.1A).

Stickleback. Stickleback have been documented in the upper KR mainstem (Table 15.1-46). Observations included threespine stickleback and unidentified stickleback reported in April and July. Given the presence of ninespine stickleback in the NFK and SFK, this species and threespine stickleback may constitute the unidentified specimens. Overall, 10 juvenile stickleback were observed in addition to three fish from an indeterminate life stage (Appendix 15.1B, Table B.19-2).

15.1.7 Summary

Thirteen independent fish resource studies were conducted in the mine study area from 2004 through 2008. Habitat surveys covered more than 150 miles (240 km) of riverine habitats and documented that the NFK, SFK, and UT are riffle and run dominated systems with limited mainstem channel pool habitat. Off-channel habitats are abundant and provide rearing habitat in the forms of pool and beaver pond that arenot as available in mainstem channels. Riparian vegetation is primarily composed of shrub species with little forested area. Thus, instream fish cover is provided primarily by overhanging vegetation and undercut banks. Fish population surveys documented at 15 different species within the mine study area: five anadromous salmonid species, four resident salmonid species, five resident non-salmonid species, and one lamprey species. The SFK watershed supported the most diverse fish species assemblage (14 species), although the NFK and UT watersheds supported similar fish assemblages (12 species each).

The greatest abundance of anadromous salmonids were documented in the UT, with the greatest abundances observed for coho and sockeye salmon. Pacific salmon counts in the NFK and SFK were generally an order of magnitude less than those in the UT, although Chinook salmon was the most abundant Pacific salmon in these rivers in some years. Pacific salmon were widely distributed throughout the mainstem rivers. However, in the SFK, there is an ephemeral reach that demarcates a break in Pacific salmon distributions. Only small numbers of adult Pacific salmon were observed above this ephemeral reach and only in high water years when the reach does not completely dry. The distribution of Pacific salmon appears to largely coincide with the distribution of seeps and springs.

The fish studies conducted from 2004 through 2008 resulted in the expansion of the known distribution of anadromous fish species in the Mine Study Area and provided supporting information for existing anadromous streams. Using the ADF&G's 2009 AWC as a baseline, 22 new anadromous streams were nominated, including eight, five, and nine streams in the NFK, SFK, and UT watersheds, respectively (ADF&G, 2010). The anadromous distribution was extended in an additional 14 streams, with five, two, and seven of those streams located in the NFK, SFK, and UT watersheds, respectively. The total lineal distance of nominated streams (new and extended distributions) was 23.1 miles (37.2 km). By watershed, the distribution of stream length nominated was 7.4 miles (11.9 km) in the NFK, 1.9 miles (3.1 km) in the SFK, and 13.9 miles (22.4 km) in the UT.

15.1.9 Glossary

Adfluvial—A migratory population of freshwater fish that move from lake environments where they rear and mature into flowing streams and rivers where they spawn and develop early life history stages.

Age 0+—Age of fish less than one- year old, or young-of-the-year, subyearling fry.

Age 1+—Age of fish older than one- and younger than two-years old, or yearling.

Age 2+—Age of fish older than two- but younger than three- years old.

Alluvial—Valley floor material formed by riverine flood deposition of fine and coarse sediments.

Alluvial Fan—Fan of coarse and fine sediment deposited by alluvial means at a rapid change in gradient, typically occurring from steep to shallow gradients like at the terminus of a tributary stream.

Anadromous—Fish species that reside in marine waters but migrate into freshwater for spawning and rearing of early life history stages.

ASCI—Alaska Stream Condition Index; a macroinvertebrate collection method adapted from the U.S. EPA rapid bioassessment protocols.

Baseline—For this report; baseline represents the pre-development watershed situation, including physical, chemical and biological conditions, between 2004 and 2008.

Beaver Complex—A series of interconnected ponds and/or stream channels created by beaver dams.

Channel Geometry—The form or shape of a stream channel, including the contours of its bed.

Channel Morphology—The form or shape of a stream channel, including the contours of its bed.

Colluvial—Valley floor material formed by hillside erosion and deposition of fine and coarse sediments from material transported by gravity.

Confined (Contained) Channels—A channel with restricted freedom to erode its banks and migrate laterally across the floodplain or valley floor, a narrow ratio of floodplain or valley width to channel bankfull width.

Confluence—A place where two or more streams join to flow together.

Cottid—Fishes belonging to the family Cottidae.

Downcut—The fluvial action of a stream in cutting through or scouring its bed material.

Ephemeral Stream—Streams with temporary surface water flow.

Exceedence Flow—The flow level at which the stream flow is surpassed a given percent of the time. For example, an 80 percent exceedence flow is the flow value which all other stream flow values are greater 80 percent of the time. The percent exceedence and the stream flow level are inversely proportional; that is to say, the lower the flow, the greater the percent exceedence, and vice versa.

Flashy—A flashy stream is one that exhibits significantly increased flows immediately following the onset of a precipitation event and a rapid return to pre-rain conditions shortly after the end of the precipitation. That is to say, water that precipitates within a flashy stream's watershed will make its way quickly from the land into the stream and be flushed through the system rapidly.

Fluvial Geomorphology—Study of landforms produced by stream action.

Fish Production—The conversion of energy into fish mass. Total weight or abundance of fish in a given area.

Freshwater Residence Time—The time an adult salmon lives within its natal spawning stream. This factor is used as the base period a salmon is visible on the spawning grounds to surveyors in the Area-Under-The-Curve (AUC) methodology to assess salmon spawning escapement estimates.

Gaining (Stream) Reaches—Stream reaches where groundwater influx is generating increasing surface water flows.

Geomorphology—The study of the evolution and configuration of landforms.

Glacial Drift Deposits—Sand, gravel, boulders, etc. moved and deposited by a glacier or by water arising from its melting ice.

Hanging Deltas –Alluvial deposits at the mouth of a river that are truncated by fluvial or glaciated processes.

Intermittent Stream—Stream with periodic surface water flows.

Kettle Ponds—Landforms occurring as the result of blocks of ice calving from the front of a receding glacier and becoming partially to wholly buried by glacial outwash. When the ice blocks melt, kettle holes are left in the outwash.

Lacustrine—Material deposited by or settled out of lake waters and exposed by the lowering of water levels or the elevation of land.

Lentic—Still water habitats, such as reservoirs, lakes, ponds, swamps, wetlands.

Life History Stage (Form)—Stage of fish as they pass through the various phases of their life cycle.

Life History Strategies –Species expression of various spatial and temporal strategies during their life cycle to cope with environmental conditions.

Losing (Stream) Reaches—Stream reaches where surface water is lost to subsurface layers or groundwater in unconsolidated stream bed materials.

Macroinvertebrates (Aquatic Invertebrates)—Organisms without a backbone that are large enough to be seen without the aid of a microscope.

Mainstem Channel—The principal channel of a river into which other rivers in the watershed flow.

Median—The middle value (if the total number of values is odd) or the average of the two middle values (if the total number of values is even) in an ordered list of values. Half of the values are less than the median and half are greater than the median.

Moraine—An accumulation of material which has been transported or deposited by ice. Transportation of material may occur in three ways: on the surface of the ice, in the ice, and beneath the ice.

Non-Salmonid Fishes—Fishes belonging to any family other than Salmonidae.

Off-Channel Habitat—Aquatic habitats located beyond a river's main channel, yet still within the river's active valley.

Orographic—Change in climatic conditions due to topographic influences.

Outwash Deposits—Sedimentary deposits resulting from the melting action of glaciers.

Pacific Salmon—Fish species belonging to the genus *Oncorhynchus*. In the Bristol Bay region of Alaska, there are five species of Pacific salmon: Chinook (*O. tshawytscha*), chum (*O. keta*), coho (*O. kisutch*), pink (*O. gorbuscha*), and sockeye salmon (*O. nerka*).

Palustrine—Channel type with very little flowing water; marsh-like.

Periphyton—Micro-algae that are attached to rocks or other solid surfaces.

Physiography—Study discipline pertaining to the physical patterns and processes of landform shape and evolution.

Planform –The outline or shape of the channel line in the stream-wise direction, projected on the horizontal plane as viewed from above. Often referring to channel shape (e.g., straight, braided, sinuous, meandering, planebedded, etc.).

Radio Tagging—The act of tagging radio-transmitters to species.

Radio Telemetry—The use of various types of radio-transmitters (VHF, satellite, or GPS) attached to species to track their movements.

Resident Fishes—Fish that reside its entire life cycle in the local freshwater stream network.

Salmon Escapement—The number of salmon of a specific species arriving at a natal stream or river to spawn.

Salmonid—Fishes belonging to the Family Salmonidae.

Seep—A wet place where a liquid, usually groundwater, oozes from the ground to the surface. Seeps are usually not flowing.

Spatial Distribution—Distribution of a particular parameter across the landscape.

Spawning Escapement—Number of fish escaping ocean and riverine fisheries to return to the spawning grounds to spawn.

Spring—Any natural occurrence where water flows to the surface of the earth from below the surface. Thus, a spring is where the aquifer surface meets the ground surface. Springs usually have a flow rate associated with their surface water discharge.

Stream Network—The spatial configuration of streams, including mainstem and tributary channels, within a given watershed or basin.

Stream Terrace—A flat topped, geologically older, fluvially-formed surface, situated at a higher elevation than the contemporary floodplain.

Study Transects—Survey lines extending across the streams for sampling channel characteristics.

Subsistence Fisheries—Fisheries designed for the private consumption of gathered fish.

Taxa—A taxonomic category or group, such as a phylum, order, family, genus or species.

Temporal Distribution—Distribution of species over time; typically referring to routine seasonal changes experienced during the year.

Terminal Moraines—Deposit of sediment left behind from the terminal (leading) edge of a glacier.

Tertiary—The first geologic period of the Cenozoic Era, usually subdivided into the Paleogene and the Neogene and characterized by the formation of major mountain ranges and the first grasses and grasslands.

Total Inshore Run—The estimated number of anadromous fish of a specific species returning to freshwater to spawn; calculation can include harvest and escapement estimates.

Transect Weighting Factor—Instream flow transects, representing a specific habitat feature, were weighted in accordance with the frequency of the specific habitat type in the study reach.

Tributary—A river or stream that flows into a larger river or stream or other waterbody.

Unconfined Channel—A channel with freedom to erode its banks and migrate laterally across the floodplain or valley floor, a large ratio of floodplain or valley width to channel bankfull width.

Watershed Processes—Physical or chemical processes that provide an overarching influence on habitat characteristics in a watershed (i.e., geologic, hydrologic, fluvial, erosion, sediment transport, heat input, etc.).

Velocity Shelter—A location within a stream at which the flow velocity is reduced, such that it provides a refuge or shelter to fish. Velocity shelters are usually created by an upstream flow obstruction (e.g., boulders, instream vegetation, woody debris) or by the reduced flow associated with the margins of a stream channel. These locations of reduced flow enable fish to expend less energy on holding their stream position and thereby serve as resting areas.

Mainstem Channel Flow Habitat Studies	KR, NFK, SFK, UT	KR, NFK, SFK, UT		KR, NFK, SFK, UT	NFK, SFK, UT

Investigation	Year				
	2004	2005	2006	2007	2008
Off-Channel Flow Habitat Studies		SFK	SFK	UT	NFK
Water Temperature Monitoring/Modeling	NFK, SFK, UT	NFK, SFK, UT	NFK, SFK, UT	NFK, SFK, UT	NFK, SFK, UT
Fluvial Geomorphology and Spawning Gravel Quality		SFK, UT		KR, NFK, SFK, UT	NFK, SFK, UT

Notes:

a. The rainbow trout radio telemetry study was centered around Iliamna Lake downstream to the upper extent of tidal influence in the Kvichak River, with special emphasis on the Lower Talarik Creek and the UT.

KR = Koktuli River mainstem

NFK = North Fork Koktuli River

SFK = South Fork Koktuli River

UT = Upper Talarik Creek

TABLE 15.1-2
Watershed Areas of the North Fork Koktuli River, South Fork Koktuli River, Upper Talarik Creek, and Koktuli River within the Mine Study Area as Compared to Major River Systems in the Bristol Bay Drainage

River	Total Watershed Area (square miles)	Percent of Major River System	Percent of Bristol Bay Drainage [a]
NFK [b]	113	0.9	0.3
SFK [b]	107	0.8	0.3
KR [b, c]	218	1.7	0.6
Nushagak River	12,735	100	32.5
UT [d]	135	1.7	0.3
Kvichak River	8,017	100	20.1

Notes:

a. Total Bristol Bay Drainage is estimated at 39,184 square miles.

b. Within the Nushagak River System.

c. Watershed area for KR includes the portion of watershed within the mine study area, excluding the NFK and SFK watersheds.

d. Within the Kvichak River System.

KR = Koktuli River mainstem

NFK = North Fork Koktuli River

SFK = South Fork Koktuli River

UT = Upper Talarik Creek Sources:

TABLE 15.1-5
United States Forest Service Alaska Region Channel Type Legend

Code	Description
Palustrine Process Group	
PA1	Narrow Placid Flow Channel
PA2	Moderate Width Placid Flow Channel
PA3	Shallow Groundwater Fed Slough
PA4	Flood Plain Backwater Slough
PA5	Beaver Dam/Pond Channel
Flood Plain Process Group	
FP1	Uplifted Beach Channel
FP2	Foreland Uplifted Estuarine Channel
FP3	Narrow Low Gradient Flood Plain Channel
FP4	Low Gradient Flood Plain Channel
FP5	Wide Low Gradient Flood Plain Channel
Glacial Outwash Process Group	
GO1	Glacial Outwash Flood Plain Side Channel
GO2	Large Meandering Glacial Outwash Channel
GO3	Large Braided Glacial Outwash Channel
GO4	Moderate Width Glacial Channel
GO5	Cirque Channel
Alluvial Fan Process Group	
AF1	Moderate Gradient Alluvial Fan Channel
AF2	High Gradient Alluvial Cone Channel
AF8	Glacial Alluvial Cone Channel
Large Contained Process Group	
LC1	Low Gradient Contained Channel
LC2	Moderate Gradient Contained Narrow Valley Channel
Moderate Gradient Mixed Control Process Group	
MM1	Narrow Mixed Control Channel
MM2	Moderate Width Mixed Control Channel
Moderate Gradient Contained Process Group	
MC1	Narrow Shallow Contained Channel
MC2	Moderate Width and Incision, Contained Channel
MC3	Deeply incised Contained Channel
High Gradient Contained Process Group	
HC1	Shallowly Incised Muskeg Channel
HC2	Shallowly to Moderately Incised Footslope Channel
HC3	Deeply Incised Upper Valley Channel
HC4	Deeply Incised Muskeg Channel
HC5	Shallowly Incised Very High Gradient Channel
HC6	Deeply Incised Mountainslope Channel

Code	Description
HC8	Moderate/High Gradient Glacial Cascade Channel
HC9	High Gradient Incised Glacial Torrent Channel

Notes:

Channel Type naming conventions:

Deeply Incised = over 33 feet (10 meters)

High Gradient = 6 -15 percent

Low Gradient = less than 2 percent

Moderate Gradient = 2 - 6 percent

Moderate Width = 33 - 66 feet (10 - 20 meters)

Moderately Incised = 16.5 – 33 feet (5 - 10 meters)

Narrow Width = less than 33 feet (10 meters)

Shallowly Incised = less than 16.5 feet (5 meters)

Very High Gradient = over 15 percent

Wide = over 66 feet (20 meters)

Notes:

a. Maximum number of samples collected, actual number of samples varies by constituent.

b. Data source is EBD Appendix 9.1C, *Surface Water Results*. When constituents were at levels below the Method Detection Limit, a value equal to one half of the Method Detection Limit was reported. Thus, some of minimum values shown here may represent half of the Method Detection Limit value. Method Detection Limit values vary by constituent and method of detection.

c. Data source is Zender Environmental Science and Planning Services (2006).

d. Data source is United States Geological Survey (2008).

e. Data source is Brabets and Riehle (2003).

f. Data source is Brabets (2002).

g. Data source is Vohden (1997).

h. Data source is Maurer (1987).

˚C = degrees Celsius

µS/cm = microSiemens per centimeter

mg/L = milligrams per liter

NTU = Nephelometric Turbidity Units.

— = Not available.

TABLE 15.1-12
Fish Species Found in the North Fork Koktuli Watershed, 2004-2008

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
Chum salmon	*Oncorhynchus keta*
Coho salmon	*Oncorhynchus kisutch*
Sockeye salmon	*Oncorhynchus nerka*
Arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
Rainbow trout	*Oncorhynchus mykiss*
Round whitefish	*Prosopium cylindraceum*
Whitefish [a]	*Coregoninae*
Sculpin [b]	*Cottus* sp.
Northern pike	*Esox lucius*
Ninespine stickleback	*Pungitius pungitius*
Threespine stickleback	*Gasterosteous aculeatus*

Notes:

a. Identified to subfamily, may include round whitefish, humpback whitefish, and least cisco.

b. Identified to genus, may include slimy sculpin and coastrange sculpin.

TABLE 15.1-26
Fish Species Found in the South Fork Koktuli Watershed, 2004-2008

Common Name	**Scientific Name**
Chinook salmon	*Oncorhynchus tshawytscha*
Chum salmon	*Oncorhynchus keta*
Coho salmon	*Oncorhynchus kisutch*
Sockeye salmon	*Oncorhynchus nerka*
Arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
Rainbow trout	*Oncorhynchus mykiss*
Whitefish [a]	*Coregoninae*
Sculpin [b]	*Cottus* sp.
Northern pike	*Esox lucius*
Ninespine stickleback	*Pungitius pungitius*
Threespine stickleback	*Gasterosteous aculeatus*
Burbot	*Lota lota*
Lamprey [c]	*Lampetra* sp.

Notes:

a. Identified to subfamily, may include round whitefish, humpback whitefish, and least cisco.

b. Identified to genus, may include slimy sculpin and coastrange sculpin.

c. Identified to genus, may include Arctic and Pacific lamprey.

TABLE 15.1-38
Fish Species Found in the Upper Talarik Watershed, 2004-2008

Common Name	**Scientific Name**
Chinook salmon	*Oncorhynchus tshawytscha*
Chum salmon	*Oncorhynchus keta*
Coho salmon	*Oncorhynchus kisutch*
Sockeye salmon	*Oncorhynchus nerka*
Pink salmon	*Oncorhynchus gorbuscha*
Arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
Rainbow trout	*Oncorhynchus mykiss*
Whitefish [a]	*Coregoninae*
Sculpin [b]	*Cottus* sp.
Ninespine stickleback	*Pungitius pungitius*
Threespine stickleback	*Gasterosteus aculeatus*

Notes:

a. Identified to subfamily, may include round whitefish, humpback whitefish, and least cisco.

b. Identified to genus, may include slimy sculpin and coastrange sculpin.

PHOTOGRAPHS

PHOTO 15.1-1: Surveys were completed to document the types, quality, and quantity of aquatic habitats present in streams and tributaries within the mine study area. Data were collected for mainstem channels (A), side channels (B), and split channels (C).

PHOTO 15.1-2: Several fish sampling methods were employed to document and describe patterns of fish distribution and relative abundance of juvenile (A) and adult salmonids in the proposed mining area. Sampling techniques included beach seines (B), snorkel surveys (C), electrofishing surveys, minnow traps, fyke nets, gill nets, tangle nets, and angling.

PHOTO 15.1-3: Snorkel surveys were calibrated using multi-pass electrofishing depletion sampling (A). Electrofishing was also used in sample sections not conducive to snorkeling (B). Captured fish were identified to species, measured (C), and released.

PHOTO 15.1-4: Images from helicopter surveys to enumerate adult salmon in the North Fork Koktuli, South Fork Koktuli, and Upper Talarik watersheds.

PHOTO 15.1-5: Radiotelemetry studies have been conducted to document movement and behavioral patterns of arctic grayling and rainbow trout within streams within the mine study area. These photos depict plane-based mobile tracking (A), a stationary tracking station (B), and surgical implanting of radio tag transmitters (C).

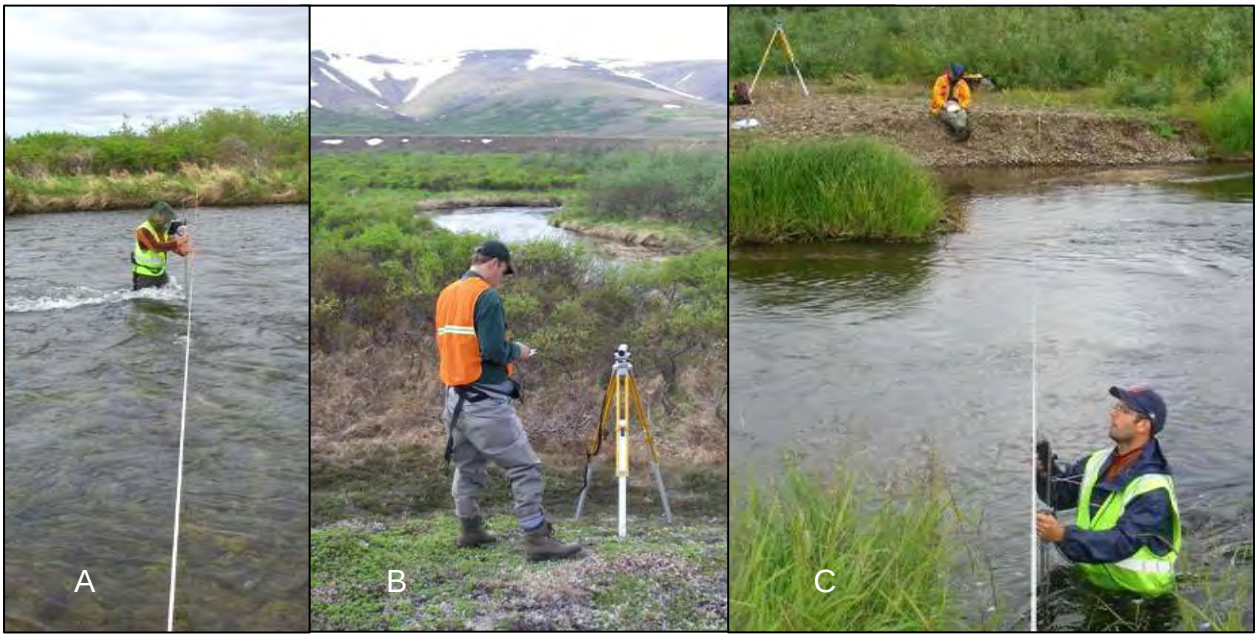

PHOTO 15.1-6: Instream flow habitat studies to determine habitat versus flow relationships for various target fish species and life stages have been conducted on each of the mainstem rivers in the mine study area, including the North Fork Koktuli River (A), South Fork Koktuli River (B), and Upper Talarik Creek (C), as well as selected tributaries.

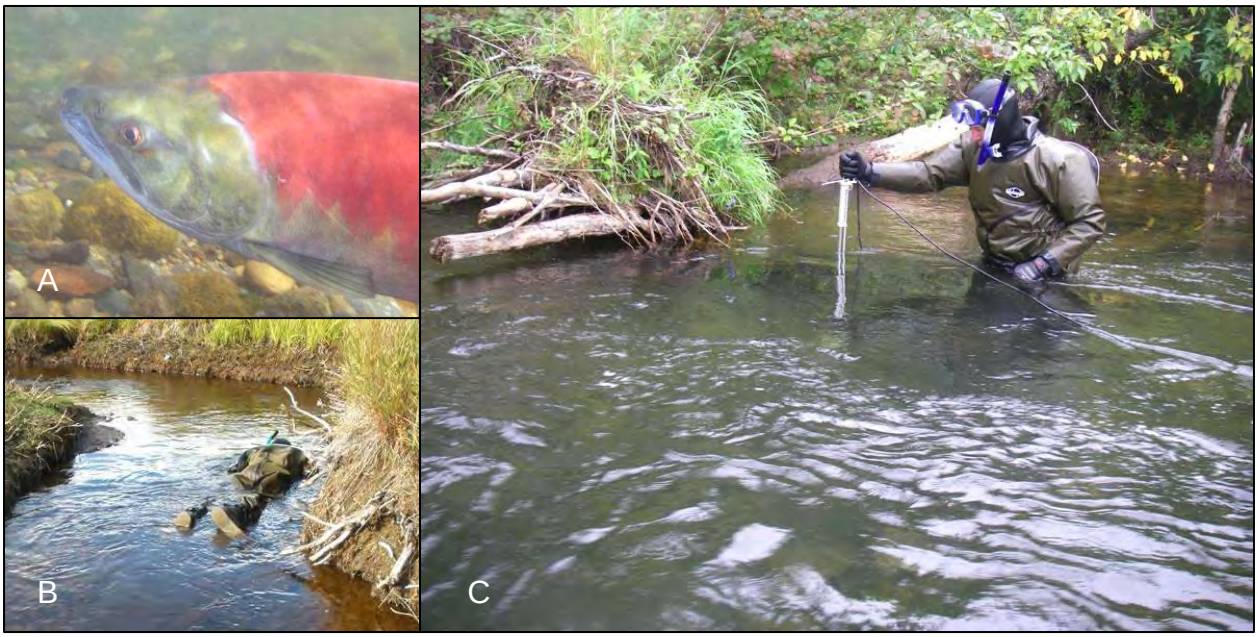

PHOTO 15.1-7: Microhabitat data were collected from spawning (A) and juvenile rearing (B) habitats and applied in developing site-specific Habitat Suitability Criteria curves for use in the instream flow habitat studies. Site-specific microhabitat data collection included measuring depth, velocity, substrate, and cover

(C).

PHOTO 15.1-8: Studies to evaluate and quantify off-channel habitats (A) and their connectivity (B) and flow responsiveness (C) to mainstem channel flows have been conducted in each of the three main drainages of the mine study area, including the North Fork Koktuli, South Fork Koktuli, and Upper Talarik.

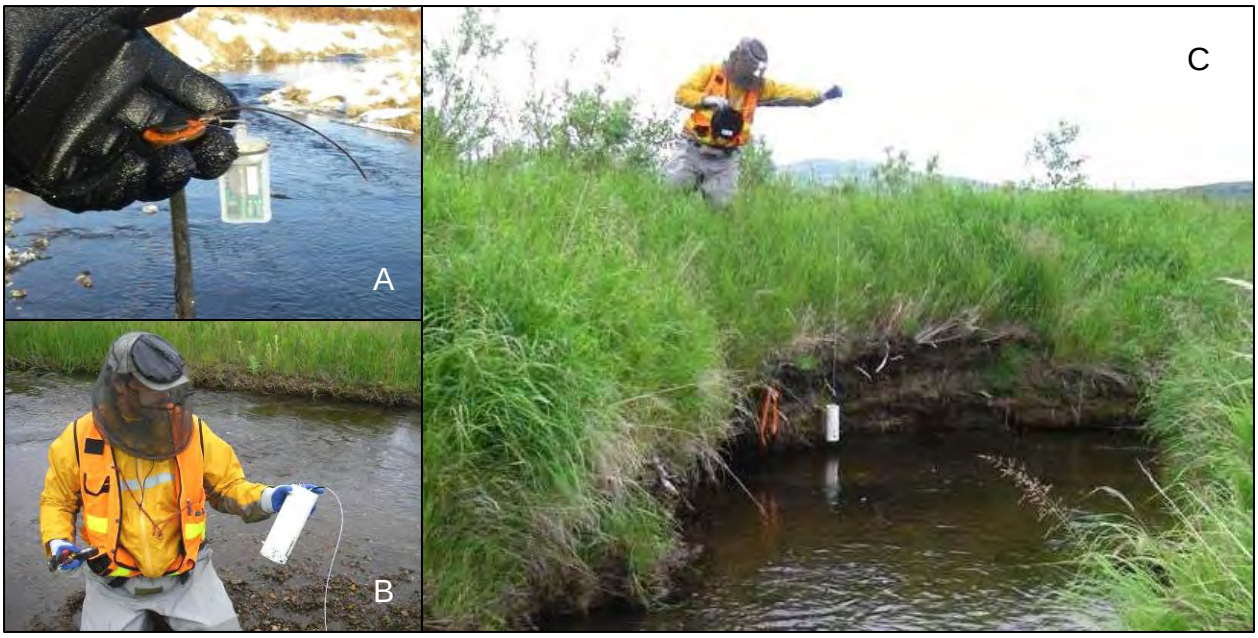

PHOTO 15.1-9: Water temperatures were monitored at numerous locations within each of the three watersheds (North Fork Koktuli, South Fork Koktuli, and Upper Talarik). Intragravel thermistors (A) and surface thermistors within a protective housing of PVC pipe (B) were installed in both mainstem channel and off-channel (C) habitats.

PHOTO 15.1-10: Fluvial geomorphology studies served to characterize the quality of spawning gravels by identifying the concentrations of fine sediments within the gravel matrix (A). Bulk substrate samples were collected from each of the mainstem rivers (North Fork Koktuli River, South Fork Koktuli River, and Upper Talarik Creek) before spawning (B) and after fall high flows prior to winter freeze-up (C).

FISH SPECIES LIFE HISTORY INFORMATION

1. CHINOOK SALMON, *ONCORHYNCHUS TSHAWYTSCHA*

1.1 CURRENT DISTRIBUTION

Chinook salmon are distributed from northern Hokkaido, Japan, to the Anadyr River in Siberia and from the San Joaquin River in Central California to the Coppermine River in the Canadian Arctic (Healey, 1991). In Alaska, Chinook salmon occur in large coastal rivers from the southern tip of Alaska's panhandle northward to Point Hope (Mecklenburg et al., 2002). Chinook salmon have been documented in several Bristol Bay tributaries, including the Kvichak and Nushagak river basins (Johnson and Weiss, 2007).

1.2 BEHAVIOR AND REPRODUCTION

As with other Pacific salmon, Chinook salmon are anadromous—meaning they reproduce and spend the early portion of their life in freshwater then metamorphose into smolts that migrate to sea for a period of adult growth, development, and maturation. Chinook salmon mature and begin their spawning migration between 3 and 6 years of age, but most spawning adults are ages 4 and 5 (Healey, 1991). In northwestern Canada and Alaska, adult Chinook salmon migrate to freshwater spawning grounds between late May and July, although this period may extend from April to September in some locations (Healey, 1991). While spawning generally takes place from July to November, spawning time varies regionally and depends on the distance and duration of river migration (Morrow, 1980; Scott and Crossman, 1973). Northern populations, such as those in Alaska, tend to spawn from July through September (Healey, 1991). Adults die following reproduction and egg deposition into one or more gravel nests known as redds.

Chinook salmon egg incubation varies with temperature, with lower temperatures resulting in increased time to hatching (Healey, 1991). After hatching in the spring, the young remain in the gravel for 2 to 3 weeks and then emerge as free-swimming, feeding fry (Morrow, 1980). While some juvenile Chinook salmon may rapidly disperse to sea, this life history pattern tends to be absent in locations north of 56 degrees North latitude, such as Alaska (Quinn, 2005). In these northern locations, most juvenile Chinook salmon remain in freshwater streams for 1 year before beginning their outmigration to sea, but some will remain in freshwater for 2 years (Morrow, 1980; Quinn, 2005).

1.3 HABITAT REQUIREMENTS

Owing to their large body size, adult Chinook salmon require deep holding water and sufficient stream flow to successfully complete their upstream migration. Spawning depths vary widely, from 5 to 720 centimeters (cm), with average spawning depths starting at 30 cm (Healey, 1991). The large body size of Chinook salmon also enables them to use large gravel and cobble substrates for spawning (Raleigh et al., 1986). Successful incubation requires clean water percolating through spawning gravels at temperatures less than 16 degrees Celsius (°C) (Healey, 1991).

Juvenile Chinook salmon occupy a variety of habitats during their stay in freshwater. Younger, smaller fry inhabit stream margins, eddies, backwaters, and side channels and are often associated with fallen trees, root wads, and areas with bank cover. As they increase in size, juvenile Chinook salmon move into stream and river habitats with increasing velocities (up to 1.2 meters per second). This movement is associated with a shift from predominantly sandy substrates to those with larger-sized gravel and boulders (Healey, 1991).

2. CHUM SALMON, *ONCORHYNCHUS KETA*

2.1 CURRENT DISTRIBUTION

Chum salmon have the widest distribution among the Pacific salmon, ranging from Korea to the Lena River in Russia and from the Mackenzie River in the Canadian Arctic down to Monterey, California. On the Pacific coast of North America, major chum salmon runs occur from the Kotzebue Sound of northwestern Alaska southward to Tillamook Bay, Oregon., There are major runs in Bristol Bay tributaries, including the Togiak, Nushagak, and Kvichak rivers (Salo, 1991). While chum salmon do not typically migrate long distances in freshwater reaches, some populations extend over 2 kilometers into tributaries of the Mackenzie and Yukon rivers (Quinn, 2005).

2.2 BEHAVIOR AND REPRODUCTION

Like other Pacific salmon species, chum salmon are anadromous. Compared to other Pacific salmon, they spend little time in freshwater and generally spawn soon after returning from the sea to lower stream reaches (Quinn, 2005). Chum salmon are typically fall spawners. However, in Alaska and northwestern Canada, spawning migration begins in early June (McPhail and Lindsey, 1970), and in Bristol Bay tributaries, major chum salmon runs tend to peak in early July and subside by the end of the month (Salo, 1991). Spawned-out males and females die within a few days after reproduction and egg deposition, although females may first attend their redds for a short period of time (Morrow, 1980).

Chum salmon incubation times are largely based on temperature. Since chum salmon juveniles hatch out under the cover of ice, the exact timing of hatching in Alaska is largely unknown. In British Columbia, hatching occurs between December and February (McPhail and Lindsey, 1970; Morrow, 1980). Hatchlings remain in the gravel for several weeks. After emergence, juvenile chum salmon rear in freshwater for a period of a few days to several weeks before migrating downstream toward estuarine waters (Grette and Salo, 1986). Generally, chum salmon outmigration occurs between mid-spring and late summer, but it tends to occur later in the season in more northern latitudes and takes longer in larger river systems (Salo, 1991). Juvenile chum salmon spend more rearing time in estuaries than other anadromous salmon, rearing for several months before dispersing into saltwater in late July or August (Johnson et al., 1997; Scott and Crossman, 1973). Chum salmon mature between 2 and 6 years of age (Salo, 1991).

2.3 HABITAT REQUIREMENTS

Chum salmon have been reported to spawn in shallower, lower flow streams and side channels compared to other Pacific salmon (Johnson et al., 1997). Chum salmon typically spawn over gravel substrates (2 to 3 cm in diameter), although coarser substrates may also be used (Morrow, 1980). Preferred spawning

areas are in groundwater-fed streams or at the head of riffles (Grette and Salo, 1986). Groundwater upwelling is important to redd site selection (Johnson et al., 1997). Health of the emergent chum salmon fry depends on dissolved oxygen, gravel composition, spawner density, and stream discharge (Salo, 1991).

Juvenile chum salmon move out of freshwater shortly after emergence and feed on aquatic invertebrates as they migrate downstream (Salo, 1991). Juveniles may remain near the mouth of their natal river after entering the estuary, or they may disperse rapidly throughout the estuarine system into tidal creeks and sloughs. Because of their increased rearing time in estuaries, estuarine habitat is thought to play a major role in determining subsequent adult return to freshwater (Johnson et al., 1997). A variety of microhabitats and food sources within the estuary may be used by chum salmon, and microhabitat selection may vary with fish size and environmental conditions such as food and refugia availability, predator presence, and salinity (Quinn, 2005).

3. COHO SALMON, *ONCORHYNCHUS KISUTCH*

3.1 CURRENT DISTRIBUTION

Coho salmon are widely distributed throughout the North Pacific basin. Their distribution ranges from the Sea of Japan north to Point Hope, Alaska, and south to the Sacramento River in California (Sandercock, 1991). Along the Pacific coast of Alaska, coho salmon are native to coastal rivers and streams, including the Kvichak and Nushagak river basins.

3.2 BEHAVIOR AND REPRODUCTION

Like other Pacific salmon species, coho salmon are anadromous. North American coho salmon typically spawn from October to March, although entry into freshwater and spawning time varies among populations and with environmental conditions (Morrow, 1980; Sandercock, 1991). In northwestern Canada and Alaska, adult coho salmon may begin their upstream migrations as early as late June and July; however, most of the spawning in these areas occurs in November. In the Bristol Bay area, adult returns to freshwater peak in August and September (McPhail and Lindsey, 1970) and spawning continues through the fall. Coho salmon adults die after spawning.

The length of incubation for coho salmon ranges from 35 to 101 days (Laufle et al., 1986). Specific to Alaska coho salmon, the incubation period ranges from 42 to 56 days (McPhail and Lindsey, 1970). After hatching, larval fish typically spend 2 to 3 weeks in the gravel before emerging between early March and mid-May (Laufle et al., 1986; McMahon, 1983). Juvenile coho salmon rearing time in freshwater is typically about 15 months, although some juveniles will remain in freshwater for up to 2 years (Sandercock, 1991). Smolt outmigration begins in February and may continue into June; however, in more northern populations, outmigration is likely to occur later and extend into July or August. While the majority of coho salmon reach maturity and return from the sea to reproduce in their natal tributaries as 3-year olds, precocious males that reach maturity during their first (referred to as “jacks”) or second year are a natural component of many Alaska coho populations (Sandercock, 1991).

3.3 HABITAT REQUIREMENTS

Adult coho salmon require deep holding cover for resting during upstream migration, as well as sufficient stream flow for upstream movement into tributaries. A minimum depth of 18 cm is needed for upstream migration of coho salmon (Laufle et al., 1986). Coho salmon spawning gravels are typically less than 15 cm in diameter, and optimal incubation temperatures range from 4°C to 11°C (Sandercock, 1991).

Newly emerged fry usually congregate along stream margins and in backwater pools. As juveniles grow, they disperse and aggressively defend their territory, which results in displacement of excess juveniles downstream to potentially less favorable habitat (Sandercock, 1991). Once territories are established, individuals typically rear in selected areas of the stream, feeding on drifting benthic organisms and terrestrial insects until the following spring (Hart, 1973). During their first winter, juveniles use a variety of slower water habitats –including alcoves, beaver ponds, and side channels (Nickelson et al., 1992). In the winter, this habitat provides low-velocity refuge from high flows. During summer low-flow periods, exposed complex large wood structures and side channels are important habitats for coho salmon (Grette and Salo, 1986).

4. PINK SALMON, *ONCORHYNCHUS GORBUSCHA*

4.1 CURRENT DISTRIBUTION

Pink salmon are widely distributed along the Pacific rim of Asia and North America, from Japan to North Korea, and from central California north to the Bering Sea. The range of this species also extends east and west of the Bering Strait as far as the Lena River in northern Siberia and the Mackenzie River delta in Canada (Heard, 1991). The most abundant North American populations are found in coastal rivers from the Fraser River in southern British Columbia north to the Norton Sound in Alaska (Quinn, 2005). In the Bristol Bay area, pink salmon are abundant (McPhail and Lindsey, 1970).

4.2 BEHAVIOR AND REPRODUCTION

Like other Pacific salmon species, pink salmon are anadromous. However, relative to other salmon species, pink salmon spend very little time in freshwater and display minimal variation in spawning age (McPhail and Lindsey, 1970; Quinn, 2005). Almost all pink salmon spawning occurs when fish are 2 years of age, resulting in reproductively isolated populations between even and odd spawning years. In a particular stream, it is common for either the even- or odd-year run to predominate, although in some streams, the populations may be equally abundant. In the Bristol Bay watershed, the even-year runs tend to predominate. In Alaska, pink salmon adults return to their natal rivers for spawning from June through September, with peak migrations occurring in July and August. Spawning times range from July through September (Heard, 1991). Adults die after spawning.

Pink salmon incubation times, which largely depend on temperature, range from 2 to 4 months, and hatching occurs between late December and February (Morrow, 1980). After hatching, alevins spend several weeks in the gravel before the fry emerge in April and May (McPhail and Lindsey, 1970). Upon emergence, pink salmon fry immediately migrate downstream (Heard, 1991). The young salmon spend

the next 18 months to 2 years at sea as they grow, develop, and mature before returning to their natal rivers (Scott and Crossman, 1973).

4.3 HABITAT REQUIREMENTS

Pink salmon generally spawn in the tidal areas and lower reaches of large rivers and their smaller tributaries (Heard, 1991; McPhail and Lindsey, 1970; Mecklenburg et al., 2002). Spawning takes place over redds with medium to small gravels, and in streams with moderate to fast stream flows (ranging from 30 to 140 centimeters per second) and depths of 30 to 100 cm (Heard, 1991; McPhail and Lindsey, 1970; Scott and Crossman, 1973). For successful embryonic development, temperatures above 4.5°C are needed (Morrow, 1980).

Because pink salmon fry outmigrate immediately upon emergence, they tend to feed very little in freshwater, but when they do, they consume insect larvae (McPhail and Lindsey, 1970). Before moving further off-shore, fry may occupy estuarine habitats for a short period of time where they are opportunistic and generalized feeders (Heard, 1991).

5. SOCKEYE SALMON, *ONCORHYNCHUS NERKA*

5.1 CURRENT DISTRIBUTION

Sockeye salmon populations occur in Asia from the Kuril Islands north to the Gulf of Anadyr, and in North America from the Sacramento River in California to Point Hope, Alaska (Burgner, 1991). In North America, sockeye salmon are primarily distributed from the Columbia River north to the Kuskokwim River in Alaska (Quinn, 2005). Among the Alaska and northwestern Canada populations, one of the largest spawning sockeye salmon complexes occurs in Alaska's Bristol Bay basin (McPhail and Lindsey, 1970). Some sockeye salmon live entirely in freshwater and are referred to as kokanee salmon. In Alaska, kokanee salmon are distributed from the southern tip of Alaska's panhandle to the Kenai Peninsula, which lies just east of Bristol Bay (Mecklenburg et al., 2002).

5.2 BEHAVIOR AND REPRODUCTION

Sockeye salmon are unique among other *Oncorhynchus* species in that the rearing of juveniles largely takes place in lakes. Spawning usually occurs in streams connected to lakes, although some populations spawn in lakes (Morrow, 1980). The Bristol Bay basin contains a large number of lakes and, consequently, large spawning complexes of sockeye salmon. Life history characteristics of these populations have been well studied (Burgner, 1991). In the Bristol Bay basin, adult sockeye salmon runs occur from early June to August, with 80 percent of the run occurring within a 12- to 14-day period (Burgner, 1991). Spawning takes place in August and September (McPhail and Lindsey, 1970). Eggs are deposited into redds, and adults die after spawning.

Sockeye salmon egg incubation takes between 6 and 9 weeks, and as with other salmon species, incubation time depends on temperature (McPhail and Lindsey, 1970). After spending 2 to 3 weeks in the gravel redd, sockeye salmon fry move either upstream or downstream into a lake associated with the spawning stream. The fry will rear for 1 to 2 years in the lake, where they will grow and begin to smolt

(McPhail and Lindsey, 1970; Quinn, 2005). The seaward outmigration of sockeye salmon smolts begins after ice break-up. In the Bristol Bay basin, peak outmigrations occur in June when water temperatures are around 4°C (McPhail and Lindsey, 1970; Morrow, 1980). Adults return to natal streams for spawning after spending 1 to 4 years at sea (Mecklenburg et al., 2002).

5.3 HABITAT REQUIREMENTS

Because juvenile sockeye salmon typically rear in freshwater lakes, adults tend to spawn in systems associated with lakes. Stable flow conditions appear to be an important criterion for sockeye salmon spawning, particularly when juveniles must migrate upstream to reach their lake-rearing habitats (Burgner, 1991). Spawning habitats are diverse and include lake inlet and outlet rivers, lake beaches, and spring-fed ponds and side channels, all of which offer stable flow conditions (Burgner, 1991; Quinn, 2005). Redds may be constructed in a variety of substrates, ranging from fine gravels in side channels to coarse lake shore gravels and rocky beaches (Burgner, 1991).

Recently emerged sockeye salmon fry may move directly into open water, or they may occupy the shallower water along the shoreline for a period of time as they transition into deeper lake habitats (Burgner, 1991). Diversity in prey item availability is reflected in the diets of juvenile sockeye salmon. For juveniles in littoral zones, dipteran insects are a primary food item, while zooplankton are an important food source in the limnetic zone (Burgner, 1991; McPhail and Lindsey, 1970).

6. RAINBOW TROUT, *ONCORHYNCHUS MYKISS*

6.1 CURRENT DISTRIBUTION

Rainbow trout are native to both Asia and North America. In Asia, they occur naturally on the Kamchatka Peninsula. In North America, rainbow trout distribution ranges from northwest Mexico to the Kuskokwim River in Alaska (Mecklenburg et al., 2002). Rainbow trout have been widely introduced on all continents. In the Alaska interior, introductions have been made to freshwater habitats near Fairbanks, Big Delta, and Summit Lake (Morrow, 1980). The distribution of native populations in Alaska extends from the Alaska panhandle along the coastline north to the Kuskokwim River and west to the Point Moller region of the Alaska Peninsula (Mecklenburg et al., 2002). While both anadromous and nonanadromous populations occur throughout most of this range, the majority of the Bristol Bay populations are nonanadromous (Quinn, 2005); the few anadromous populations of steelhead documented in the Bristol Bay watershed occur in the southernmost part of the watershed, south of Port Heiden (ADF&G, 2010). The life history discussion below focuses exclusively on nonanadromous rainbow trout.

6.2 BEHAVIOR AND REPRODUCTION

Resident rainbow trout are spring spawners. Adults tend to stay relatively close to their natal streams, and their spawning migrations are reportedly short (only a few kilometers; Morrow, 1980). Spawning takes place between mid-April and late June. Rainbow trout deposit eggs and sperm into redds, but unlike other *Pacific salmon* species, rainbow trout are iteroparous (can breed multiple times) and adults do not die shortly after spawning. Repeat spawning is common for resident rainbow trout (Quinn, 2005), and annual spawning may occur for up to 5 consecutive years for some fish (Morrow, 1980).

Rainbow trout incubation times typically range from 4 to 7 weeks, depending on water temperature. Fry emergence occurs within 3 to 7 days, and is usually between mid-June and mid-August (Morrow, 1980). After emergence, lake-resident rainbow trout fry may quickly disperse to lake habitats or remain in the stream for up to 3 years (McPhail and Lindsey, 1970; Scott and Crossman, 1973). Rainbow trout mature at an age of 3 to 5 years and may live for up to 9 years (Morrow, 1980).

6.3 HABITAT REQUIREMENTS

Rainbow trout can be either stream- or lake-resident fish. When in rivers and streams, rainbow trout are commonly found near lake outlets or below waterfalls and rapids (McPhail and Lindsey, 1970). Tributary streams are used as spawning habitat by both stream- and lake-resident populations (Morrow, 1980). Redds are often constructed in fine gravel substrates of riffles adjacent to pools. Preferred spawning and incubation water temperatures are between 10°C and 13°C, and groundwater upwelling and dissolved oxygen concentrations are important in determining egg survival rates (McPhail and Lindsey, 1970; Morrow, 1980). Juveniles from stream-resident populations occupy riffles during the summer months and tend to shift into pools for the autumn and winter months (McPhail and Lindsey, 1970).

Rainbow trout are opportunistic predators that feed on a wide variety of prey items. Prey items include various insects (e.g., dipteran larvae and adults), plankton, crustaceans, snails, leeches, fish eggs, smaller fishes, and even adult salmon carcasses (Morrow, 1980; Quinn, 2005; Scott and Crossman, 1973).

7. ARCTIC CHAR, *SALVELINUS ALPINUS*

7.1 CURRENT DISTRIBUTION

The arctic char is a circumpolar species, with a wide distribution that includes northern North America, northern Asia, northern Europe, Iceland, Greenland, and other arctic islands (Scott and Crossman, 1973). In Alaska, this species ranges from the Kenai and Alaska peninsulas, and the Aleutian and Kodiak islands, north to arctic Alaska drainages (Mecklenburg et al., 2002; Morrow, 1980). Both anadromous and nonanadromous forms of arctic char occur in northern North America. In much of Alaska, arctic char populations appear to be nonanadromous and confined to lakes (Morrow 1980).

7.2 BEHAVIOR AND REPRODUCTION

The arctic char is an iteroparous species and exhibits both anadromous and nonanadromous life histories, but direct evidence of anadromy in Alaskan populations is lacking (Mecklenburg et al., 2002). In the Bristol Bay region, some populations of arctic char are thought to be permanent lake-dwelling residents (McPhail and Lindsey, 1970). Anadromous arctic char begin their upstream spawning migration in late summer and early fall (i.e., from late July to early September), and spawning occurs in lakes and rivers in the fall, usually from September to October (McPhail and Lindsey, 1970; Quinn, 2005). Nonanadromous and lake-dwelling arctic char also spawn during from September to October. Following spawning and egg deposition, adults from both anadromous and nonanadromous populations overwinter in freshwater lakes and streams. For anadromous stocks, seaward return migrations are not made until the following spring (Quinn, 2005; Scott and Crossman, 1973). Adults of this iteroparous species may spawn annually or, as is often the case with females, only every second or third year (Scott and Crossman, 1973).

Egg incubation and embryonic development occur over the winter and may potentially last until ice break-up in spring. Newly hatched young remain in the gravel for 60 to 70 days, after which emergence occurs and fry begin active feeding (Morrow, 1980). Young char rear in freshwater for several years, with their first outmigration occurring at 5 to 7 years (McPhail and Lindsey, 1970). Arctic char may live for up to 20 years or more (Quinn, 2005).

7.3 HABITAT REQUIREMENTS

Arctic char spawning habitat can be varied and includes gravel shoals in lakes and pools with walnut-sized gravel, as well as riverine gravel beds located downstream from rapids (McPhail and Lindsey, 1970). This broad range of suitable habitats suggest a large tolerance for varied stream velocities as well. The thermal tolerance of Arctic char is well documented. Actual spawning takes place when water temperatures are near 4°C; water temperatures ranging from 3°C to 8°C are needed for successful embryonic development (Morrow, 1980; Quinn, 2005; Scott and Crossman, 1973). Prior to outmigration, young char occupy the rocky shores of lakes and streams (McPhail and Lindsey, 1970). For anadromous stocks, adult char may use estuaries or coastal areas near their natal streams as summer habitat, but direct evidence of such habitat use is lacking. Regardless of anadromy, most arctic char prefer to overwinter in freshwater lakes that are not necessarily the same as their natal sites (Quinn, 2005).

Arctic char are largely carnivorous and opportunistic feeders in that they often consume any available vertebrates and invertebrates that are small enough to be eaten (Scott and Crossman, 1973). Adults feed primarily on other fishes and benthic organisms such as young arctic char, young sockeye salmon, sticklebacks, chironomid larvae, and gastropods Young char may prey more heavily upon amphipods and insect larvae (McPhail and Lindsey, 1970; Scott and Crossman, 1973).

8. DOLLY VARDEN, *SALVELINUS MALMA*

8.1 CURRENT DISTRIBUTION

Dolly Varden are distributed in Asia from Japan and North Korea north to the Kamchatka and Chukchi peninsulas. In North America, Dolly Varden are found from northern Washington along the Pacific and arctic coasts to the Mackenzie River in Canada (Mecklenburg et al., 2002; Quinn, 2005). Two forms of Dolly Varden are recognized and are morphologically distinguishable by their gill-raker and vertebrate numbers (Mecklenburg et al., 2002). The two forms, a southern and a northern form, are geographically separated by the Alaska Peninsula. Alaska populations of the northern form range from Bristol Bay drainages north to the arctic coast (Mecklenburg et al., 2002). In Bristol Bay drainages, both anadromous and nonanadromous populations are thought to occur (McPhail and Lindsey, 1970).

8.2 BEHAVIOR AND REPRODUCTION

Dolly Varden exhibit a wide variety of life history, migration, and habitat use patterns, although there are some consistencies among populations found along the Pacific coast of Alaska. All Dolly Varden are iteroparous fall spawners, although northern forms spawn only every 2 to 3 years and southern forms spawn annually (Morrow, 1980; Quinn 2005). Spawning occurs from late August through November in river systems that may or may not contain lakes. The incubation time for Dolly Varden eggs is

approximately 130 days at 8.5°C, and fry emergence takes place 60 to 70 days after hatching (Morrow, 1980).

Following emergence, Dolly Varden fry behavior depends largely upon whether the fry belong to an anadromous or nonanadromous stock. For anadromous populations, juveniles remain in the river or river-lake system for 3 to 4 years before migrating seaward. Smolt outmigration occurs from early spring through July, and in some systems a second fall outmigration occurs. Because anadromous adult Dolly Varden overwinter in freshwater habitats after spawning, these adults outmigrate in the spring with the smolts. Time spent at sea is highly variable, ranging from 2 weeks to 7 months. Returns to freshwater may be solely for overwintering, or for both overwintering and spawning purposes. For stream-resident (i.e., nonanadromous) populations, knowledge of migratory patterns within the freshwater system is lacking, but it has been suggested that these fish occupy deep pools in the winter and larger reaches of streams in the summer. Northern and southern forms of Dolly Varden reach maturity at 7 to 9 years and at 4 to 6 years of age, respectively (Morrow, 1980).

8.3 HABITAT REQUIREMENTS

Juvenile and adult Dolly Varden migration patterns are difficult to characterize due the diversity of behaviors and life history patterns. Freshwater river systems with and without lakes are used by both juveniles and adults for various purposes (Morrow, 1980). For example, some Dolly Varden may spawn in a non-lake stream, yet overwinter in a river-lake system. Also, juveniles tend to migrate into several different streams after returning from a sea migration (Morrow, 1980). Dolly Varden spawn in streams with water temperatures ranging from 5.5°C to 6.5°C and with clean gravel ranging in size from 0.6 to 5 cm in diameter. Redds are usually located in streams with moderately strong currents and water depths greater than 30 cm recently emerged fry occupy the bottoms of pools and eddies (Morrow, 1980).

The freshwater prey of juvenile and adult Dolly Varden includes many insects, spiders, and annelids, in addition to snails, clams, fish eggs, and small fish. Fry consume various prey, including mayfly and midge larvae, winged insects, and small crustaceans (Morrow, 1980).

9. LEAST CISCO, *COREGONUS SARDINELLA*

9.1 CURRENT DISTRIBUTION

The least cisco occurs in both Asia and North America. Its Asian distribution ranges from the White Sea on the northwest coast of Russia east to the Bering Strait. In North America, least cisco populations are found in coastal areas from the Bristol Bay drainage of Alaska, north along the arctic coast and east to Bathurst Inlet and Cambridge Bay in Canada. In Alaska, inland populations are found in lakes and streams north of the Alaska Range, and in the Kuskokwim and Yukon River drainages (Mecklenburg et al., 2002). The least cisco has been characterized as having two distinct and largely geographically separated (allopatric) forms: an anadromous, migratory form common in coastal waters, and a nonmigratory, lake-dwelling form. In the Bristol Bay region of Alaska, migratory forms are present. In addition, dwarf versions of the nonmigratory form have been documented in Iliamna and Naknek lakes (McPhail and Lindsey, 1970).

9.2 BEHAVIOR AND REPRODUCTION

Both anadromous and nonanadromous least cisco spawn in September and October (Morrow, 1980). The anadromous spawning runs occur from early July to late September (Morrow, 1980). At the spawning site, a female may be joined by one or two males (and sometimes more) as she swims upward toward the surface and releases her eggs. Males release milt, and the fertilized eggs settle into the gravel crevices below. Spawned adults of migratory populations may then begin to move downstream to return to coastal waters, although little is known about migration distances or the habitats used along the way (Scott and Crossman, 1973).

Least cisco eggs incubate through the winter and hatch in the spring (McPhail and Lindsey, 1970). Feeding and habitat utilization behaviors of the newly hatched young are unknown, but it has been noted that by mid-June, large numbers of fry move downstream to deeper slower water. Sexual maturity is attained at 2 to 4 years of age, with most maturing after 3 years (Morrow, 1980). Least cisco may live for 8 to 11 years (Morrow, 1980), although in some instances fish over 20 years old have been reported (Scott and Crossman, 1973).

9.3 HABITAT REQUIREMENTS

Nonmigratory forms of least cisco are primarily lake dwellers and are common in large lakes and rivers (McPhail and Lindsey, 1970). Migratory forms are common in streams and in coastal and brackish waters (Morrow, 1980). Shallow rivers and lake shores with gravel and sand bottoms are used as spawning habitat (Morrow, 1980; Scott and Crossman, 1973). Spawning has been noted to occur in water with depths ranging from 1.3 to 2.6 meters, an average velocity of approximately 50 centimeters per second, and surface temperatures of 0°C to 3°C (Morrow, 1980). After hatching, fry from migratory populations move downstream to deeper and slower waters (Morrow, 1980; Scott and Crossman, 1973).

Least cisco primarily feed on planktonic crustaceans (e.g., amphipods, cladocerans, and mysids). River populations also rely on aquatic and terrestrial insects of various stages (Morrow, 1980; Scott and Crossman, 1973). Plant material may also be consumed (Morrow, 1980).

10. HUMPBACK WHITEFISH, *COREGONUS PIDSCHIAN*

10.1 CURRENT DISTRIBUTION

Humpback whitefish are distributed along the arctic coast from the Kara Sea in northern Siberia to the Sagavanirktok River in Alaska (Mecklenburg et al., 2002). In Alaska, distributional records for this species should be considered with caution due to potential species identification errors and confusion with other whitefish species (Morrow, 1980). It is generally accepted that humpback whitefish in Alaska range from the Kuskokwim River northward along the coast to the Bering, Chukchi, and western Beaufort Sea drainages (Mecklenburg et al., 2002; Morrow, 1980). Humpback whitefish populations also extend to inland reaches of the Kuskokwim and Colville River basins (Mecklenburg et al., 2002). Species distribution maps (Mecklenburg et al., 2002; Page and Burr, 1991) and a recent study (Woody and Young, 2007) indicate that this species is also found within the Bristol Bay drainage basin.

10.2 BEHAVIOR AND REPRODUCTION

Details regarding the life history and anadromy of humpback whitefish are confounded and limited, largely as a result of a systematic debate as to whether *C. pidschian* is distinct from or belongs to the *C. clupeaformis* species complex. While it has been maintained that *C. pidschian* differs from the other two species in the complex in modal gill-raker numbers, it is also possible that *C. pidschian* represents a truly anadromous form, and *C. clupeaformis* and *C. nelsoni* represent primarily lake- and stream-dwelling forms, respectively (Morrow, 1980). Mecklenburg et al. (2002) and Morrow (1980) recognize *C. pidschian* as a distinct species, and the life history account given here also recognizes this distinction.

Humpback whitefish are thought to be mostly anadromous, although some populations may reside entirely in freshwater (Mecklenburg et al., 2002; Morrow, 1980; Woody and Young, 2007). Upstream spawning runs begin in June, and spawning takes place from October to mid-November. Presumably, humpback whitefish demonstrate a spawning behavior similar to that of the Alaska whitefish (*C. nelsoni*), which involves a female being accompanied by one or more males as she swims toward the surface and releases her eggs. Fertilized eggs settle into the interstitial gravel substrate. Hatching is assumed to occur in late winter and spring, and the fry move downstream. Upon reaching sexual maturity between the ages of 4 and 6, mature fish return to their natal sites for spawning and may do so for multiple spawning seasons throughout their lives (Morrow, 1980). The life expectancy for humpback whitefish may be 20 years or more (Woody and Young, 2007).

10.3 HABITAT REQUIREMENTS

Humpback whitefish inhabit rivers, lakes, and near-shore coastal waters, and overwintering takes place near the mouths of rivers (Mecklenburg et al., 2002; Woody and Young, 2007). Migration patterns, distances traveled, and the habitats used along the way are largely unknown. However, humpback whitefish have been taken at sea several kilometers out, and others have been taken from upstream locations that signify migration distances of up to 1,600 kilometers (Mecklenburg et al., 2002; Morrow, 1980). Research in the Lake Clark and Kvichak River system suggests that some populations of humpback whitefish reside entirely in freshwater, and that some individuals may migrate to low-salinity estuarine habitats (Woody and Young, 2007). Specific spawning habitat conditions are also unknown.

Humpback whitefish have a limited diet. Adults mostly consume mollusks, crustaceans, and chironomid larvae. Young humpback whitefish feed largely on zooplankton (Morrow, 1980).

11. ROUND WHITEFISH, *PROSOPIUM CYLINDRACEUM*

11.1 CURRENT DISTRIBUTION

Round whitefish are distributed in freshwater locations in Asia from the Yenisei River east and south to the Kamchatka Peninsula. In North America, round whitefish range from mainland Alaska east to Canada and the western shore of the Hudson Bay. Other North American populations are found in the Great Lakes and from Labrador to Connecticut. Round whitefish have a broad distribution throughout mainland Alaska north of the Taku River near Juneau (Mecklenburg et al., 2002).

11.2 BEHAVIOR AND REPRODUCTION

Round whitefish begin their spawning activities with inshore or upstream migrations to spawning beds that may be either lake shores or gravelly river shallows (Morrow, 1980). The exact timing of these migrations and actual spawning appears to vary among locales and latitudes (Scott and Crossman, 1973). Generally, spawning occurs throughout the fall season, from September to December, and from late September through October in interior Alaska. Males and females pair prior to the act of spawning, and females broadcast their eggs such that fertilized eggs settle into rock and gravel crevices. No parental care is given to the eggs or young, and it is presumed that adults move out of the spawning beds shortly after spawning. Spawning occurs annually and in successive years for many adult round whitefish (Morrow, 1980).

Incubation lasts for approximately 140 days at a water temperature of 2.2°C (Scott and Crossman, 1973). Hatching occurs in spring, and newly hatched larvae absorb their yolk sacs for 2 to 3 weeks before they leave the spawning grounds. Maturity is attained between the fifth and seventh years. A maximum lifespan of at least 16 years has been reported for round whitefish (Morrow, 1980).

11.3 HABITAT REQUIREMENTS

Round whitefish is a predominantly freshwater species, with rare accounts in brackish waters (Mecklenburg et al., 2002). These whitefish primarily inhabit low flow habitats such as shallow areas of lakes, clear rivers, and streams (Mecklenburg et al., 2002). Spawning habitats include shallow inshore lake areas and shallow gravelly river mouths and shores (Scott and Crossman, 1973). However, in some southern parts of its range, round whitefish uncharacteristically occur in deep lakes and spawn in deeper waters (Scott and Crossman, 1973).

Round whitefish feed in shallow and inshore areas (McPhail and Lindsey, 1970). These benthic feeders primarily consume the immature stages of insects, particularly dipterans, chironomids, and caddisflies (Morrow, 1980; Scott and Crossman, 1973). To a lesser degree, adult caddisflies, small mollusks, cladocerans, and small fish are also consumed (Morrow, 1980; Scott and Crossman, 1973). There are also reports of the round whitefish feeding heavily on the eggs of other fish species such as lake trout, chum, suckers, and shad (McPhail and Lindsey, 1970).

12. ARCTIC GRAYLING, *THYMALLUS ARCTICUS*

12.1 CURRENT DISTRIBUTION

Arctic grayling occur in mainland Asia and North America. In Asia, they are distributed east of the Ob and Kara rivers in Siberia and north of the Eroo River in northern Mongolia. The North American distribution of arctic grayling includes Alaska and northern Canada eastward to Hudson Bay, and they have also been documented in the Missouri River headwaters of Montana (Mecklenburg et al., 2002). Arctic grayling occur naturally throughout most of Alaska and are also found on the St. Lawrence and Nunivak islands (Mecklenburg et al., 2002; Morrow, 1980).

12.2 BEHAVIOR AND REPRODUCTION

Prior to spawning, arctic grayling must make an upstream migration from the deeper waters of lakes rivers where they have overwintered to spawning areas located in smaller and shallower tributaries (Morrow, 1980; Scott and Crossman, 1973). Arctic grayling prepare for their spawning migration by congregating at tributary mouths and may begin migration via channels cut in the ice by surface runoff. Little is known about arctic grayling migration distances, but movements of up to 160 kilometers have been documented (Morrow, 1980). In Alaska and northwestern Canada, spawning takes place from early May to mid-June (McPhail and Lindsey, 1970). While no formal nest is constructed by the female, a shallow depression results from the tail-quivering reproductive behavior. Eggs and sperm are released over this depression (Morrow, 1980). After spawning, adults may return to lakes or rivers, or they may migrate further upstream to occupy stream pools for a summer feeding season (Morrow, 1980; Scott and Crossman, 1973). For those that migrate further upstream, a downstream return migration to overwintering sites takes place in mid-September (Morrow, 1980). Arctic grayling spawn multiple times over their lifespan, which may be as long as 11 or 12 years (Scott and Crossman, 1973).

Arctic grayling eggs hatch after 11 to 21 days, and active feeding by the young begins 3 to 8 days after hatching (Morrow, 1980; Scott and Crossman, 1973). Information regarding the movement of juveniles away from their natal sites is lacking, but presumably they occupy seasonal habitats similar to those occupied by adults. Sexual maturity can occur as early as 4 years of age, although, maturity is more commonly attained at 6 to 9 years (Scott and Crossman, 1973).

12.3 HABITAT REQUIREMENTS

Arctic grayling occupy freshwater habitats, preferring clear, cold water in lakes, large rivers, and rocky streams (Mecklenburg et al., 2002). Arctic grayling tend to remain near rocky shores and stream mouths in lakes and are often found midstream a short distance below the surface in streams (McPhail and Lindsey, 1970). Grayling are found predominantly in low velocity habitats such pools, spring fed channels and backwaters (Hubert et al 1985). Some arctic grayling use upstream pools as summer feeding habitat, and most overwinter in the deep waters of lakes and mainstem channels. Juveniles are thought to occupy similar seasonal habitats as adults, but territorial behaviors of larger fish and prey item availability are likely to limit juvenile fish distribution and lead to habitat partitioning (Morrow, 1980). Arctic grayling adults usually spawn in small tributaries with water temperatures around 7°C to 10°C and with gravelly and rocky substrates, but they also use mainstem channels with gravel substrates and silt-laden vegetated pools below riffles (Mecklenburg et al., 2002; Scott and Crossman, 1973).

Adult arctic grayling rely heavily on aquatic and terrestrial insects (e.g., mayflies, caddisflies, grasshoppers, and beetles) as prey items, but they also exhibit opportunistic feeding patterns (McPhail and Lindsey, 1970; Morrow, 1980). Young fish mainly consume zooplankton and, as they grow, gradually shift to feeding on immature insects (Scott and Crossman, 1973).

13. NORTHERN PIKE, *ESOX LUCIUS*

13.1 CURRENT DISTRIBUTION

The northern pike is a circumpolar freshwater species with a wide distribution in the northern hemisphere. In Alaska, it is widespread in the Arctic Ocean and Bering Sea drainages south to the Bristol Bay basin. It has also been introduced into the Ahrnklin and Susitna River drainages, and into lakes and streams on the Kenai Peninsula and around Anchorage (Mecklenburg et al., 2002).

13.2 BEHAVIOR AND REPRODUCTION

In early spring, just after ice melt occurs, adult northern pike move inshore or upstream to marshy, vegetated, and mud-bottomed spawning sites (Morrow, 1980). Actual spawning occurs in April to early May (Scott and Crossman, 1973). Following courtship, egg deposition and fertilization take place such that eggs are scattered on weedy vegetation or a muddy substrate. Over the next several days, repeated acts of spawning are common for both males and females. While no parental care is provided to the incubating eggs, most fully spawned adults do not leave the spawning area for 6 weeks, and some may linger for as long as 14 weeks. This species generally does not migrate, except for relatively short distances into and out of spawning areas (Morrow, 1980).

As with many other fish species, time to hatching for northern pike depends on water temperature. With a water temperature of 6°C, 23 to 29 days may be needed for hatching, whereas only 4 to 5 days may be needed at a temperature of 18°C (Morrow, 1980). Lacking a fully developed mouth, newly hatched pike larvae absorb their yolk sac over the next 6 to 10 days while clinging to weeds or the bottom via an adhesive gland on their heads (Scott and Crossman, 1973). The young then become active feeders and remain near their natal site over the next several weeks. Northern pike in more northern locations tend to grow more slowly, mature later, and live longer than their southern counterparts. In Alaska, age at maturity is thought to be 3 to 4 years (Morrow, 1980). The average life expectancy f northern pike ranges from 10 to over 20 years (Scott and Crossman, 1973).

13.3 HABITAT REQUIREMENTS

Northern pike reside in a variety of freshwater habitats with slow-moving waters, such as clear vegetated lakes, and quiet pools and backwaters of streams and rivers (Mecklenburg et al., 2002). From fall through spring, shallow waters less than 5 m deep are generally preferred, but in the heat of summer pike may move into deeper, cooler habitats (Scott and Crossman, 1973). Spring spawning sites are typically shallow vegetated areas (e.g., marshes, river floodplains, and bays of lakes) with depths less than 51 cm, and most spawning activity occurring at depths less than 25 cm. Suitable vegetation and quiet water appear to be the two most important factors in spawning site selection. Young pike less than 20 millimeters in length remain near the spawning ground for initial rearing, although high fry mortality is common and likely due to competition for food, predation, cannibalism, and water quality factors (e.g., pH, and carbonate and bicarbonate concentrations; Morrow, 1980).

Northern pike are voracious carnivores that feed primarily on other fish, including their own species. Food choice is largely based on availability. In Alaska, major prey items include whitefish, small pike, blackfish, burbot, suckers, dragonflies and damselflies (Morrow, 1980). Adults may also consume water

fowl, frogs, small mammals, and crayfish (Morrow, 1980). Newly hatched northern pike feed on various zooplankton and immature aquatic insects, and after 7 to 10 days they also begin to prey on small fish (Scott and Crossman, 1973). A juvenile northern pike's diet shifts with growth such that fish become an increasingly larger portion of their diet.

14. COASTRANGE SCULPIN, *COTTUS ALEUTICUS*

14.1 CURRENT DISTRIBUTION

The coastrange sculpin is distributed in North America from Alaska to southern California and is found in isolated populations in Washington and British Columbia. In Alaska, the known range extends south from Bristol Bay and east from Attu Island, including the Alaska Peninsula, and there is an isolated population in the Kobuk River in the arctic region of northwestern Alaska (Morrow, 1980; Mecklenburg et al., 2002). Coastrange sculpin have also been observed in Iliamna Lake, Naknek Lake, and Lake Aleknagik which drains into the Wood River, a tributary of the Nushagak River (Foote and Brown, 1998; Froese and Pauly, 2010).

14.2 BEHAVIOR AND REPRODUCTION

Coastrange sculpin spawning occurs between mid-February and August, peaking in May and June. Males court one or more females, who depart after depositing their eggs in rock crevices or the undersides of logs, cutbanks, or rocks (Morrow, 1980). Male coastrange sculpin guard nests of up to 7,000 eggs during the 10- to 20-day incubation period (Mason and Machidori, 1976; Morrow, 1980). Within hours of hatching, the larvae float to the water surface and assume a pelagic lifestage for approximately 30 days before becoming benthic for the remainder of their lives (Mason and Machidori, 1976). Sexual maturity is reached at age 3 and coastrange sculpin as old as 8 years have been documented (Morrow, 1980). In most populations, coastrange sculpin migrate downstream to estuarine or lower river areas to spawn and return upstream to overwinter between August and December, as do yearlings after spending up to a year in the downstream habitat. Non-migrating populations remain in winter habitat to spawn (Morrow, 1980).

14.3 HABITAT REQUIREMENTS

Coastrange sculpin inhabit both fresh and brackish waters and reside in fast streams with gravel substrate; less frequently, they may also inhabit lakes with sand or silt substrates, estuaries, and near-shore coastal waters (Mecklenburg et al., 2002). Coastrange sculpin occupy both swift and slow-water habitats (Mason and Machidori, 1976). Spawning typically occurs in lower stream reaches and in estuarine habitats (Morrow, 1980). Water temperature at the time of spawning is usually between 6°C and 8°C (Ikesumiju, 1975).

Coastrange sculpin feed mostly on the larva and nymphs of insects, although they are known to be opportunistic feeders depending on the time of year and time of day (Morrow, 1980). Common insect food sources include caddisflies, stoneflies, mayflies, and midges. Ingestion of pink salmon fry, ostracods, mysids, cladocerans, amphipods, and isopods has also been reported for this species (Morrow, 1980).

15. SLIMY SCULPIN, *COTTUS COGNATUS*

15.1 CURRENT DISTRIBUTION

The slimy sculpin is distributed in Asia from the Anadyr River to the Chukchi Peninsula. In North America, this species has a broad distribution ranging from Alaska south to the upper portions of the Fraser and Columbia rivers and east to the Great Lakes basin and Labrador, and from Nova Scotia south along the East Coast to Virginia (McPhail and Lindsey, 1970). In Alaska, known locations include the Alaska mainland, St. Lawrence and Nunivak islands, and the eastern Aleutian Islands (Mecklenburg et al., 2002). Range maps in Mecklenburg et al. (2002) and in Morrow (1980) indicate that slimy sculpin are present throughout the Bristol Bay basin, and others have documented slimy sculpin in Iliamna Lake (Foote and Brown, 1998).

15.2 BEHAVIOR AND REPRODUCTION

Slimy sculpin spawn between late March and late May following ice break-up in freshwater streams and lakes. Males construct a nest, approximately 2 to 4 cm high, beneath the cover of rocks and logs. As a ripe female approaches the nest, courtship ensues, and sperm and eggs are released into the nest (Morrow, 1980). Males usually mate with two or three females, who deposit their eggs into the male's nest. The males attend their nests during incubation for approximately 30 days (Morrow, 1980; Scott and Crossman, 1973). One week after hatching, the young leave the nest and occupy habitats similar to those used by adult sculpin. Sexual maturity is normally reached at age 2, and slimy sculpin may live up to 7 years. Aside from movement into shallow spawning waters, migration seldom occurs with this species (Morrow, 1980).

15.3 HABITAT REQUIREMENTS

The slimy sculpin is a freshwater species that resides in lakes and streams (Mecklenburg et al., 2002). As lake residents, they can be found from rocky near-shore shallows to depths up to 210 m, although depths ranging from 37 to 108 m appear to be most common (McPhail and Lindsey, 1970; Mecklenburg et al., 2002). As stream residents, slimy sculpin prefer fast-flowing streams with rocky and gravelly bottoms (Mecklenburg et al., 2002; Scott and Crossman, 1973). Slimy sculpin spawning habitat typically includes rocky lake shores and gravel-bottom streams with water depths of 2 to 30 cm. Spawning occurs when water temperatures are between 4.5°C and 10°C (McPhail and Lindsey, 1970; Morrow, 1980).

The diet of the slimy sculpin is almost exclusively insectivorous (Morrow, 1980). Aquatic insect larvae and nymphs (e.g., mayflies, caddisflies, dipterans, and odonates) are primary food items for fish of all sizes, although larger fish tend to consume larger prey items (Scott and Crossman, 1973). Ingestion of crustaceans, small fish, and aquatic vegetation has also been reported for this species (Morrow, 1980, Scott and Crossman, 1973).

16. NINESPINE STICKLEBACK, *PUNGITIUS PUNGITIUS*

16.1 CURRENT DISTRIBUTION

The ninespine stickleback has a circumpolar distribution extending across the northern lowland areas of North America, Europe, and Asia. Stickleback populations in North America are distributed from Alaska east through Canada to Labrador, Baffin Island, and Greenland; along the Atlantic coast, populations extend southward to New Jersey (McPhail and Lindsey, 1970). In Alaska, ninespine stickleback inhabit coastal regions of the Gulf of Alaska, the Aleutian Islands, Bristol Bay, and the Beaufort, Chukchi, and Bering seas. Interior populations occur to the north and west of the Kenai Peninsula (Mecklenburg et al., 2002).

16.2 BEHAVIOR AND REPRODUCTION

Ninespine stickleback spawn in freshwater during spring and summer. In Alaska and northwestern Canada, spawning takes place from May to late July (McPhail and Lindsey, 1970). Because ninespine stickleback usually occupy deep water or estuarine habitats during the fall and winter season, they must migrate to their shallow water spawning grounds in early spring (Morrow, 1980). Male stickleback use a hardening secretion and fragments of aquatic vegetation to construct tunnel-shaped nests (Scott and Crossman, 1973). Nests are attached to vegetation 10 to 15 cm above the creek bottom, or on occasion they may be located on the creek bottom (Morrow, 1980). After courtship and egg deposition, the male fertilizes the eggs. Males will stay with the nest throughout incubation and the early rearing period. Females may spawn several times in a single season, either with the same male or with others, and males often construct more than one nest. After spawning or attending to the young, adults return to deep pools or estuarine habitats and remain there until the following spawning season (Morrow, 1980).

As with many other fish species, stickleback incubation times vary with water temperature; at 18°C, hatching occurs in 1 week (Morrow, 1980). The attending male may then move the newly hatched young to a nursery area, which is a loose aggregation of nest-building materials located just above the nest (McPhail and Lindsey, 1970). After roughly 2 weeks, the young disperse from the nursery area into open water. Ninespine stickleback mature in 1 to 3 years and have a lifespan of roughly 3 years, with some females living for 5 or more years (Morrow, 1980).

16.3 HABITAT REQUIREMENTS

Ninespine stickleback may occupy marine, brackish, and freshwater habitats (Mecklenburg et al., 2002). Within Alaska, they tend to be restricted to freshwater and estuarine coastal zones, make little use of pure seawater habitats, and occur in high densities in heavily vegetated areas of lakes, ponds, and pools in slow streams (Mecklenburg et al., 2002; Morrow, 1980). Less dense aggregations of ninespine stickleback can also be found near sandy and gravelly beaches or other areas with sparse vegetation (McPhail and Lindsey, 1970). During the non-spawning and winter seasons, adults inhabit deep-water habitats (i.e., down to depths of approximately 20 m; Morrow, 1980). Spawning occurs in vegetated freshwater shallows of creeks and streams with water temperatures around 11°C or 12°C. After leaving their natal sites, young of the year may take up residence in or near rooted vegetation within lakes (Morrow, 1980).

Ninespine stickleback are carnivorous. Their diet includes a variety of aquatic insect larvae, crustaceans (e.g., copepods, chironomids, and ostracods), and other invertebrates (Morrow, 1980). During the breeding season, ninespine stickleback may also consume eggs and larvae of their own species (Hynes, 1950).

17. THREESPINE STICKLEBACK, *GASTEROSTEUS ACULEATUS*

17.1 CURRENT DISTRIBUTION

The threespine stickleback distribution includes parts of North America, Asia, and Europe. In North America, threespine stickleback occur along the Pacific coast from Baja California to the Bering Strait, and along the Atlantic coast from Chesapeake Bay to Hudson Bay and the Baffin Island vicinity (McPhail and Lindsey, 1970; Mecklenburg et al., 2002). Populations in Alaska are primarily distributed in coastal regions from the southern tip of the Alaska panhandle to the Bristol Bay region and along the Aleutian Islands (Mecklenburg et al. 2002). North of Bristol Bay, threespine stickleback records tend to be rare, and completely freshwater populations do not occur north of this area (McPhail and Lindsey, 1970; Mecklenburg et al., 2002). Dense populations have been documented in the large lakes of the Bristol Bay drainage (McPhail and Lindsey, 1970).

17.2 BEHAVIOR AND REPRODUCTION

Threespine stickleback are tolerant of marine, brackish, and freshwater habitats. Populations demonstrate a spectrum of habitat use and life history patterns, ranging from anadromous populations to entirely freshwater populations (Mecklenburg et al., 2002). In Alaska, entirely freshwater populations are present (McPhail and Lindsey, 1970). The occurrence of threespine stickleback in the Gulf of Alaska up to 800 kilometers from shore indicates anadromous populations may also occur in Alaska (Morrow, 1980). Spawning migrations in anadromous populations in Alaska typically occur in June (McPhail and Lindsey, 1970). These migrations involve movement from marine or brackish waters into spawning sites where salinity may vary from 0 to 28.5 parts per thousand (Morrow, 1980). For exclusively freshwater populations, adults move to freshwater spawning shallows from their deep water overwintering habitats (Morrow, 1980). Aside from using different spawning habitats and, consequently, displaying different migration patterns, spawning behaviors among these life history forms are generally similar. In Alaska, threespine stickleback spawn primarily in June and July. The male stickleback constructs a barrel-shaped nest from plant debris and algae (Scott and Crossman, 1973). Following courtship and egg deposition into the nest, the male fertilizes the eggs and then guards the nest throughout incubation and early rearing. Females may spawn several times in a single season, either with the same male or with others, and males often attend multiple clutches or nests simultaneously (Morrow, 1980).

Embryonic development time for threespine stickleback is from 1 to 2 weeks, depending on water temperature (Morrow, 1980). The attending male keeps the newly hatched young in the nest for a few days before the young leave the nest as free-swimming fry (McPhail and Lindsey, 1970). Sexual maturity is attained most commonly at 2 years, although anadromous forms may mature earlier at 1 year (Morrow, 1980). The maximum lifespan of the threespine stickleback is 3 years (McPhail and Lindsey, 1970).

17.3 HABITAT REQUIREMENTS

The threespine stickleback is tolerant of habitats that represent a wide range of salinity. This species may inhabit streams, rivers, ponds, lakes, tidal marshes, estuaries, inshore zones, and surface pelagic zones far from shore (Mecklenburg et al., 2002; Scott and Crossman, 1973). Marine forms may be found far from the mainland or remain closer to shore. Freshwater forms are usually associated with moderate amounts of aquatic vegetation in shallow zones, but also, as is the case in lakes of the Bristol Bay drainage in Alaska, dense stickleback populations may be found living on the surface of deep waters (McPhail and Lindsey, 1970). For both anadromous and resident populations, threespine stickleback spawning grounds are typically shallow sandy bottoms, and anadromous forms display a stronger preference for more densely vegetated spawning areas. Some young fish moving toward saltwater for the first time remain near shore in sheltering vegetation through the winter, but others move as far as 800 kilometers from shore (Morrow, 1980).

Threespine stickleback are voracious and opportunistic predators that may consume just about any available animal food (Scott and Crossman, 1973). The most important food sources are zooplankton, aquatic insect larvae, and small crustaceans (Morrow, 1980).

18. BURBOT, *LOTA LOTA*

18.1 CURRENT DISTRIBUTION

The burbot, an entirely freshwater species of cod, has a circumpolar distribution. In North America, its range extends southward to approximately 40 degrees North latitude. Its native range includes all of Alaska, except for off-shore islands, and most of the Alaska panhandle (Mecklenburg et al., 2002).

18.2 BEHAVIOR AND REPRODUCTION

In Alaska and many other parts of its range, burbot spawn under ice in late January and February (Morrow, 1980). At the time of spawning, 10 to 12 males and females congregate at the spawning site to form a large mass or ball approximately 2 meters in diameter (Scott and Crossman, 1973). No pairing between the sexes occurs; sperm and eggs are released into the center of the mass. Female burbot are highly fecund and may release from 500,000 to more than 1,000,000 eggs. After fertilization, the eggs settle to the substrate and undergo an incubation period (Morrow, 1980).

Embryonic development times vary with water temperature and from population to population. Generally, hatching occurs in early spring (McPhail and Lindsey, 1970; Morrow, 1980). Sexual maturity is usually reached at ages 3 to 4, although, in the Alaska interior, maturity may occur as late as age 7. The adult burbot life expectancy is 10 to 15 years, and some may live for over 20 years (Morrow, 1980; Scott and Crossman, 1973). Burbot migration patterns are poorly known. Individuals of this relatively sedentary species appear to make pre-spawning movements toward spawning grounds and/or post-spawning movements upriver toward feeding habitats (Morrow, 1980).

18.3 HABITAT REQUIREMENTS

Burbot occupy a wide variety of freshwater habitats including deep water lakes, large rivers, small streams, elevated lakes, and low-lying ponds (McPhail and Lindsey 1970). They are found at depths ranging from 0.3-meter in shallow spawning waters to over 200 meters in deep lakes (Mecklenburg et al., 2002). Spawning typically occurs in ice-covered streams or lake shallows over a substrate of clean sand, gravel, and stones at depths ranging from 0.3 to 1.5 meters, although spawning depths may be as great as 20 meters (McPhail and Lindsey, 1970; Morrow, 1980). Surface-water temperatures at time of spawning are between 0.6°C and 1.7°C. Post-spawning and into the summer months, adults may use shallow tributaries for feeding. Age 0 and 1 fish are commonly found in tributary streams along rocky and vegetated shores (Scott and Crossman, 1973).

The burbot is a voracious nocturnal carnivore, feeding primarily on other fishes (e.g., ciscoes, sticklebacks, and whitefish) as available (McPhail and Lindsey, 1970). During the winter, large burbot may shift their diets to include more benthic macroinvertebrates. Young burbot prey heavily on aquatic invertebrates, crayfish, and mollusks, as well as numerous other food sources (Scott and Crossman, 1973).

19. LONGNOSE SUCKER, *CATOSTOMUS CATOSTOMUS*

19.1 CURRENT DISTRIBUTION

The longnose sucker is found in Asia and North America. Its Asian distribution ranges from the Yana River to Anadyr River in northern Siberia. In North America, longnose sucker is distributed throughout much of mainland Canada and Alaska, and its range extends into the contiguous United States including Washington, the Great Lakes region, and New England (Morrow, 1980). This species is common throughout mainland Alaska (McPhail and Lindsey, 1970).

19.2 BEHAVIOR AND REPRODUCTION

Longnose suckers are spring spawners. As lake ice cover begins to melt, adult longnose suckers move into their spawning sites, which are typically shallow inlet streams or swift stream reaches with gravel substrates. The seasonal timing of spawning runs and actual spawning vary with latitude such that earlier occurrences are found in the more southern locations. Generally, runs and spawning occur from April to June or July (McPhail and Lindsey, 1970; Morrow, 1980). Spawning runs typically begin when water temperatures reach 5°C, and peak runs occur when temperatures are above 10°C (Morrow, 1980). During a brief spawning act which lasts for only seconds, a female is joined by several males in the middle of the stream center, and eggs and milt are released. Fertilized eggs settle into gravel crevices in the substrate. Many of the spawned adults move away from spawning sites as early as 5 days after their upstream migration began, but some, particularly river residents, will remain in the area for much of the summer (Morrow, 1980; Scott and Crossman, 1973). Longnose suckers may spawn in consecutive years or only every second or third year (Morrow, 1980).

The incubation time for longnose suckers is approximately 2 weeks. Newly hatched young will remain in the gravel for an additional 1 to 2 weeks (Scott and Crossman, 1973). After emerging, many young

suckers move downstream, while others remain in the natal area throughout the summer months (Morrow, 1980). For longnose suckers, age at maturity tends to increase with latitude. In British Columbia and other more southern locales, maturity has been reported at ages of 2 to 7 years. In the Northwest Territories, longnose suckers mature at 9 to 10 years (McPhail and Lindsey, 1970; Morrow, 1980).

19.3 HABITAT REQUIREMENTS

Longnose suckers inhabit clear, cold freshwater. Primary habitats include lake bottoms up to 183 m deep and slow, deep pools in tributary streams. The species has also been reported in brackish waters near the mouths of rivers (Scott and Crossman, 1973). Longnose sucker spawning habitats tend to be inlet streams, lake outlets, and lake shallows with gravel substrates (McPhail and Lindsey, 1970; Morrow, 1980). Preferred environmental conditions for spawning include gravel sizes of 50 to 100 millimeters in diameter, water velocities of 35 to 40 centimeters per second, and water depths of 10 to 60 cm (Morrow, 1980).

Like other sucker species, the longnose sucker feeds as it slowly swims along the substrate, ingesting bottom debris containing benthic invertebrates (Morrow, 1980). Numerous food items are consumed by suckers, with variation resulting largely from fish size, habitat, and seasonal availability (Scott and Crossman, 1973). In stream habitats, major food sources include algae, plants, dipterans, mayflies, caddisflies, beetles, spiders, and mollusks. Longnose suckers in lake habitats commonly consume small crustaceans (e.g., cladocerans and amphipods) and insect larvae and nymphs, particularly dipterans and mayflies. Young longnose suckers feed largely on cladocerans and insects (Morrow, 1980).

20. ARCTIC LAMPREY, *LAMPETRA CAMTSCHATICA*

20.1 CURRENT DISTRIBUTION

The arctic lamprey has an almost circumpolar distribution, ranging from Finland's Province of Lapland east to Kamchatka and across the Bering Sea to the Northwest Territories of Canada. In Alaska, arctic lamprey is distributed from the Kenai Peninsula northward to arctic coast drainages and is present in the Yukon, Kuskokwim, and Tanana River drainages (Mecklenburg et al., 2002). In Bristol Bay drainages, both anadromous and freshwater forms are thought to occur (McPhail and Lindsey, 1970; Morrow, 1980).

20.2 BEHAVIOR AND REPRODUCTION

Relatively little information regarding the life history of arctic lamprey is available. This may in part be due to confusion resulting from anomalous populations that may be different lamprey species. It is generally thought that arctic lamprey are represented by both anadromous and freshwater forms. Spawning takes place in the spring (Morrow, 1980). Spawning occurs between late May and mid-July in Bristol Bay drainages (McPhail and Lindsey, 1970). Both sexes participate in constructing a shallow depression, or nest, in the gravel substrate. Using his oral disc, the male attaches onto the female's head and wraps his body around the female's body. As the mating pair quivers and vibrates, eggs and sperm are released over the nest. A female may mate several times and usually with different males (Scott and Crossman, 1973). Adults die after spawning.

Arctic lamprey eggs hatch within a few weeks. Juveniles are called ammocoetes. The juveniles lack eyes and an oral disc and burrow into soft substrates, where they will filter feed and grow for 1 or 2 years (Morrow, 1980). It is possible that the ammocoete stage can last as long as 4 years (Scott and Crossman, 1973). Juveniles metamorphose into an adult form and migrate downstream to marine waters, lakes, or large rivers, depending upon their degree of anadromy. Transformation and downstream migration take place in the fall, or from August to November. The amount of time between downstream migration and returning spawning migration is unknown (Scott and Crossman, 1973). The life expectancy of arctic lamprey is thought to be at least 3 years (Morrow, 1980).

20.3 HABITAT REQUIREMENTS

Arctic lamprey spawning occurs over gravel-bottom riffles and runs within clear stream habitats (Mecklenburg et al., 2002). Shallow nests are typically constructed out of the main stream current. Suitable flows are 16 to 30 centimeters per second (Morrow, 1980), and gravel sizes range from 13 to 51 millimeters in diameter (Scott and Crossman, 1973). Water temperatures during spawning are between 12.2°C and 15° C. Juveniles burrow into soft muddy substrates of stream margins and backwaters (McPhail and Lindsey, 1970). As adults, anadromous arctic lamprey inhabit marine environments at depths up to 50 meters (Mecklenburg et al., 2002), while freshwater populations reside in lakes and large rivers (Scott and Crossman, 1973).

Anadromous and freshwater forms of arctic lamprey are generally considered to be parasitic, although freshwater forms have blunt teeth that may limit parasitic feeding. It is also possible that some freshwater populations may have been confused with other, nonparasitic lamprey species (Morrow, 1980). When parasitism is present, arctic lamprey adults use a variety of fish species as feeding hosts. Known host species include sockeye, pink, chum, and Chinook salmon, as well as rainbow trout, starry flounder, pygmy whitefish, smelt, cisco, longnose sucker, burbot, and threespine stickleback (Morrow, 1980; Scott and Crossman, 1973). It is likely that any fish of suitable size can be used as an arctic lamprey feeding host (Morrow, 1980). Arctic lamprey juveniles filter-feed on plankton, algae, and detritus while burrowed in soft substrates (McPhail and Lindsey, 1970; Scott and Crossman, 1973).

21. PACIFIC LAMPREY, *LAMPETRA TRIDENTATA*

21.1 CURRENT DISTRIBUTION

Pacific lamprey have been documented in various areas of the North Pacific rim. Along the Pacific coast of Asia, rare to occasional records of Pacific lamprey exist from marine environments near the eastern Kamchatka Peninsula, the Commander Islands, and Hokkaido, Japan. In North America, Pacific lamprey are distributed from northern Baja California to the eastern Bering and Chukchi seas (Mecklenburg et al., 2002). However, McPhail and Lindsey (1970) found only a single specimen north of the Alaska Peninsula. The fish was taken from the Wood River in the Bristol Bay drainage basin. Other records north of the Alaska Peninsula exist for St. Matthew Island, Nome, and Cape Lisburne (Mecklenburg et al., 2002).

21.2 BEHAVIOR AND REPRODUCTION

The Pacific lamprey is largely an anadromous and parasitic species, although some landlocked and nonparasitic populations occur in California and Oregon (Mecklenburg et al., 2002). Adults of anadromous forms usually migrate upstream into freshwater habitats from July to September, although they are not reproductively mature at this time. Overwintering occurs from October to March, and actual spawning occurs sometime between April and July. Using body motions and their oral discs, sexually mature males and females construct a shallow depression in a sandy gravel substrate, usually at the upstream end of a riffle. During spawning, eggs and sperm are released over the nest, and fertilized eggs settle into the substrate. The spawning act may occur several times over the next 12 hours, and males may spawn with more than one female in different nests. Adults die 1 to 14 days after spawning (Scott and Crossman, 1973).

Pacific lamprey eggs hatch in 1 to 3 weeks, depending on water temperatures (Morrow, 1980; Scott and Crossman, 1973). Larval lamprey, ammocoetes, lack eyes and an oral disc. The juveniles burrow into a substrate of fine sand and mud downstream from the nest and feed for several years by filtering the water. After 5 to 6 years, the ammocoetes metamorphose into a parasitic, but sexually immature form that has eyes, an oral disc, and horny teeth. These individuals migrate to sea during the late summer. Parasitic behaviors begin the following spring or summer and last for 12 to 20 months, after which time fish will return to freshwater to spawn. The average lifespan of adult Pacific lamprey is at least 7 years (Scott and Crossman, 1973).

21.3 HABITAT REQUIREMENTS

Anadromous Pacific lamprey migrate upstream to spawn, sometimes traveling several hundred kilometers to headwater areas. Once in streams, Pacific lamprey rely on rocks and stones to provide cover while they overwinter and undergo reproductive maturation. Spawning habitats are usually at the upstream edges of riffles, and substrates are often fine gravel and sand (Scott and Crossman, 1973)Ammocoetes burrow in silt, sand, and mud substrates in shallow eddies and backwaters of streams for 4 to 5 years (Mecklenburg et al., 2002). Although no specific velocity preferences were found in the literature, the fact that ammocoetes burrow in fine sediments and filter feed suggests these fish would more likely be found in low velocity habitats where fine sediments would be deposited. Ammocoetesleave their burrows and metamorphose into parasitic forms that rely on late summer flood conditions to carry them out to marine or estuarine waters (Scott and Crossman, 1973).

Anadromous Pacific lamprey feed during only two stages throughout their lifespan. While burrowed in substrates of sand, silt and mud, ammocoetes feed by filtering organic material and algae from ingested water (McPhail and Lindsey, 1970). Parasitic forms feed exclusively in the marine environment by latching onto other fish or marine vertebrates using their sucking disc. No feeding occurs in freshwater during seaward outmigrations nor during upstream spawning migrations (Morrow, 1980).

23. GLOSSARY

Allopatric—occurring in separate, non-overlapping geographic areas.

Ammocoete—filter-feeding larval stage of a lamprey.

Amphipod—a member of an order of small crustaceans named so because their appendages are not all the same and found in terrestrial and aquatic environments.

Anadromous—relating to the life history characteristic in which fish reproduce and spend the early portion of their life in freshwater and then migrate to sea for a period of adult growth, development, and maturation before returning to natal spawning areas.

Anadromy—migration of adult or subadult fish from saltwater to freshwater for spawning.

Annelid—a member of the large group of segmented worms also known as ringed-worms.

Benthic—relating to the bottom or substrate of an aquatic environment.

Brackish—characterized by a mixture of freshwater and saltwater.

Chironomid—a member of a group of winged insects also known as non-biting midges.

Cladoceran—a member of a group of small crustaceans also known as water fleas.

Dipteran—a member of the insect order Dipter; includes the two-winged or "true" flies.

Emergence—departure of fish fry from the gravel or substrate into the water column.

Fry—a stage in the fish life cycle characterized by the commencement of active feeding; young newly-hatched fish.

Gastropod—a class of animals that belong to the mollusk family and include: snails, slugs, welks, conches, limpets, periwinkles, abalones, slugs, etc.

Isopod—a group of small crustaceans with flattened bodies and all similar appendages found in aquatic and terrestrial environments.

Iteroparous—capable of reproducing or breeding multiple times.

Limnetic—relating to the open water area away from the shore of a lake or pond.

Littoral—relating to the shallow shore region of a lake, sea, or ocean.

Milt—milky substance that contains sperm and is released by male fish to fertilize eggs.

Mysid—a group of small, shrimp-like, aquatic animals without backbones in the crustacean family.

Ostraocod—a class of very small aquatic animals without backbones in the crustacean family. They are bivalves like clams but are much smaller at 1 millimeter in size.

Outmigration—the migration of juvenile fish down a river system toward marine and brackish waters.

Pelagic—relating to the deeper open waters of a sea or ocean, not near the shore or bottom.

Plankton—small plants that float or drift in fresh or saltwater.

Redd—the gravel nest of salmonid fishes.

Resident—pertaining to nonanadromous, entirely freshwater fish populations.

Salmonid—any member of the fish family Salmonidae; includes salmon, trout, char, whitefish, and grayling.

Smolt—a young or juvenile fish, usually with silvery coloration, in the seaward migration phase of anadromous salmonids.

Stock—a discrete population of a fish species that tends to inhabit the same waters and breed in the same stream.

Zooplankton—small animals without backbones, mainly crustaceans and fish larvae, that float or drift in fresh or saltwater.

APPENDIX 15.1B

Reach Analysis Mine Study Area, 2004-2008

Appendix B – Reach Analysis

1.1 Introduction

Comprehensive studies in the vicinity of the Pebble Deposit were initiated in 2004 by Northern Dynasty Mines, Inc. and have been continued by the Pebble Partnership through 2008. The overall goal of the fish and aquatic resource studies was to describe baseline fish population characteristics in the mine study area and the condition of local aquatic habitats that support current fish production. Numerous studies were conducted during the five-year study period to achieve this goal. This appendix depicts the results of these fish and aquatic studies conducted within the vicinity of the Pebble Deposit and includes information on: fish distribution, mesohabitat mapping, aquatic habitat surveys, relative fish abundance, spawning distributions, winter habitat sampling, and mainstem index fish surveys. Detailed descriptions of the study area, objectives, and methods are provided in Chapter 11 of the consolidated study program for the Pebble Project (copy provided in Appendix E of this EBD).

The fish and aquatic data were collected along the length of more than 380 km of mainstem and tributary stream habitat in the North and South Fork Koktuli rivers (NFK and SFK, respectively) and Upper Talarik Creek (UT). In order to present the data within an ecologically meaningful framework, we delineated 18 distinct hydrologic reaches and summarized the fish and aquatic data that were collected within each reach. Reaches were delineated by R2 Resource Consultants, Inc. and Buell & Associates, Inc. based on a review of maps and existing data associated with multidisciplinary parameters influencing channel function. Parameters considered included: channel and valley morphology, geology, stream discharge, and surface water temperature. The review resulted in the delineation of six, five, and seven mainstem EBD reaches within the NFK, SFK, and UT, respectively (Table 1). Reach names were assigned alphabetically within each watershed, starting with reach A as the downstream most reach and moving upstream to the headwaters (Table 1). Additionally, tributaries and off-channel aquatic habitats within the three basins were assigned to one of the 18 mainstem reaches based on the location of the tributary-mainstem confluence. Each tributary drainage was assigned to the mainstem reach that it flowed into, while off-channel habitat was assigned based on its proximity to the mainstem channel. While no formal reach delineation occurred for the mainstem Koktuli River (KR), the portion of the KR for which fish and habitat data were collected during the 2004-2008 study period (Table 1) is included as its own section within this appendix and has been treated in the same manner as the other 18 delineated reaches for purposes of results analysis and presentation.

Table 1:
Delineated EBD reaches and associated river kilometers (RKm) used for the reach analysis.

EBD Reach	Downstream RKm	Upstream RKm	Appendix B Section
NFK-A	0	13.69	B.1
NFK-B	13.7	21.07	B.2
NFK-C	21.08	36.64	B.3

UT-E	36.29	45.06	B.16
UT-F	45.07	59.13	B.17
UT-G	59.14	62.38	B.18
KR	16.55	63.00	B.19

This appendix is organized into 19 reach-specific documents that depict the reach level analysis. Overall, the data analysis includes maps, tables, and figures that depict:

- reach location;
- fish sampling locations;
- habitat survey locations;
- species presence data;
- the spatial distributions of anadromous and resident fish species;
- mainstem mesohabitat mapping results;

- results of the mainstem and tributary United States Forest Service (USFS) modified Tier 1 and Tier 3 aquatic habitat surveys, including channel morphology characteristics, habitat type composition, stream habitat characteristics, pool habitat characteristics, and special habitat features;
- the temporal distributions of fish species by life stage and numbers of fish observed;
- relative fish abundance and density by habitat type within mainstem and tributary streams;
- relative fish abundance and density by channel location (i.e., main channel, side channel, off-channel);
- relative fish abundance and density by off-channel habitat types;
- anadromous fish spawning locations;
- adult anadromous fish counts from aerial spawning surveys conducted in 2008;
- winter fish sampling locations and relative fish abundance; and
- fish observations and fish density by habitat type at Mainstem Index Fish Survey sites in 2008.

The suite of maps, tables, and figures presented varies among the reaches. While some data (e.g., fish distribution and abundance surveys) were collected in all reaches, others (e.g., off-channel habitat studies) were applicable only to a subset. The presentation order of maps, tables and figures was structured to be as consistent as possible among basins within the confines of the aforementioned data differences among reaches.

The following map production notes will enhance the viewing of maps in Appendix B.

1. All maps are electronic and, although they can be printed for convenience, some detail is visible only when zoomed in to a finer scale on the electronic form. For example, some sampling locations are very close to or even adjacent to another sampling location and the marker symbols for these sites can be obscured by each other. The result is that what appears to be one sampling location marker on the map may in fact be multiple markers that are differentiated by zooming in on that area of the map.

2. Some data were collected at one point in a river and are denoted as data collection sites. Other data were collected over a length of river, i.e., sampling was continuous from point a to point b, and in this latter case the data are presented a sampling survey.

3. The Appendix B maps were created and produced in a series, thus the legend was built for the map series and, as such, contains all possible data types for that series. Furthermore, the legend for any individual reach map within a series may contain symbols for data that were not documented within that reach and thus are not depicted on the map itself.

4. The map background orthophoto was generated by aerial photogrammetric methods using aerial photographs dated July 2004. As a result, the stream network seen on the image is represented by

the way it was at one point in time during July 2004. In addition, all GPS locations have some level of error associated with them. This error is generally less for waypoints taken on the ground (on the order of a meter or two) than those taken from the air (up to 400 m). As a result of these two factors, GPS measurement error and a fixed orthophoto photo date, there are some data points on the maps that do not appear to be contained within a stream channel but are located nearby. When this data was checked for QA/QC and found to be correct, then the marker identifying that point was left where it fell on the map and was not moved to be contained within a stream channel or water body. This is particularly important to keep in mind when viewing data collected in off-channel areas.

5. To be consistent with the reach level analysis, all data points, whether they were collected from the mainstem river, a tributary draining into the mainstem, or a nearby off-channel area, are linked back to the mainstem reach for summary and analysis. The beginning and end points of the mainstem reaches were selected so as to end upstream of the closest tributary so that the data collected within that tributary would be associated with the nearest downstream mainstem reach. On the maps this may be reflected by tributary and off-channel data points that at first look appear to be outside the reach of interest however are linked to the mainstem reach by a drainage area.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.1
NORTH FORK KOKTULI RIVER REACH A (NFK-A)

Table B.1-1.
List of species found in NFK-A.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*
threespine stickleback	*Gasterosteus aculeatus*

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.1-2.
2004-2008 number of fish observations by lifestage within NFK-A mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

Species	Year	Method	Adult				Juvenile			Juvenile/Adult[a]					Total
			Jul	Aug	Sep	Subtotal	Jul	Aug	Subtotal	Apr	Jul	Aug	Sep	Subtotal	
Chinook salmon	2004	Minnow Trap						57	57						57
	2005	Minnow Trap						28	28						28
		Snorkel	1			1	4		4						5
	2006	Snorkel	3	2		5	3838	212	4050						4055
	2007	Snorkel	3			3	2182		2182						2185
	2008	Seine						1	1						1
		Snorkel		6		6		137	137						143
chum salmon	2005	Snorkel	3			3									3
	2006	Snorkel	2			2									2
	2007	Snorkel	8			8									8
coho salmon	2004	Electrofishing						3	3						3
		Minnow Trap						70	70						70
	2005	Minnow Trap						65	65						65
		Snorkel					1092		1092						1092
	2006	Snorkel					852	259	1111						1111
	2007	Snorkel					2031		2031						2031
	2008	Seine		1		1		2	2						3
		Snorkel						18	18						18
sockeye salmon	2005	Snorkel	4			4	1		1						5
	2006	Snorkel					17		17						17
	2007	Snorkel	5			5	32		32						37
	2008	Seine						1	1						1
		Snorkel		5		5									5
Pacific salmon sp.	2005	Minnow Trap						694	694						694

Table B.1-2. Continued

Species	Year	Method	Adult				Juvenile			Juvenile/Adult[a]					Total
			Jul	Aug	Sep	Subtotal	Jul	Aug	Subtotal	Apr	Jul	Aug	Sep	Subtotal	
arctic grayling	2005	Snorkel	37			37									37
	2006	Snorkel	28			28									28
	2007	Angling			9	9							3	3	12

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.2
NORTH FORK KOKTULI RIVER REACH B (NFK-B)

Table B.2-1.
List of species found in NFK-B.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.2-2.
2004-2008 number of fish observations by lifestage within NFK-B mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

Species	Year	Method	Adult				Juvenile					Juvenile/Adult[a]				Total
			Apr	Jul	Aug	Subtotal	Apr	Jul	Aug	Nov	Subtotal	Apr	Jul	Aug	Subtotal	
Chinook salmon	2005	Snorkel		1		1		204			204					205
	2006	Electrofishing								10	10					10
		Snorkel		1	3	4		609	65		674					678
	2007	Snorkel						1032			1032					1032
	2008	Seine							7		7					7
		Snorkel							119		119					119
chum salmon	2005	Snorkel		5		5										5
	2006	Snorkel		1		1										1
	2007	Snorkel		5		5										5
coho salmon	2004	Minnow Trap					17				17					17
	2005	Snorkel						2545			2545					2545
	2006	Electrofishing								4	4					4
		Snorkel						184	2		186					186
	2007	Snorkel						1614			1614					1614
	2008	Seine							2		2					2
		Snorkel							66		66					66
sockeye salmon	2005	Snorkel						1			1					1
	2006	Snorkel						2			2					2
	2007	Snorkel						41			41					41
	2008	Seine							17		17					17
arctic grayling	2005	Snorkel		46		46										46
	2006	Snorkel		16	4	20										20
	2007	Snorkel		20		20										20
	2008	Snorkel			3	3										3
Dolly Varden	2004	Minnow Trap					13				13					13
	2005	Snorkel		1		1		3			3		4		4	8
	2006	Electrofishing								10	10					10
		Snorkel						5			5					5
	2008	Snorkel							2		2					2

Table B.2-2. Continued

Species	Year	Method	Adult				Juvenile					Juvenile/Adult[a]				Total
			Apr	Jul	Aug	Subtotal	Apr	Jul	Aug	Nov	Subtotal	Apr	Jul	Aug	Subtotal	
whitefish sp.	2006	Snorkel		3		3										3
Salmonid sp.	2007	Snorkel						6			6					6
sculpin sp.	2004	Minnow Trap	2			2	1				1					3
	2005	Minnow Trap										1			1	1
	2008	Seine			2	2			16		16					18
		Snorkel												4	4	4
ninespine stickleback	2004	Minnow Trap										1			1	1

[a] This lifestage category includes subadult fish and fish whose lifestage was not, or could not, be determined.

Note: Blank cells indicate no data were collected for that record.

2008 NFK 1.190 TOTAL			3.2	1.7	2.7	0.5

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

[d] NA=data not available.

[e] Sample Area was comprised of 94% low gradient contained channel and 6% beaver dam/pond channel.

Table B.3-3.
Percent composition of primary habitat types from areas sampled within NFK-C and tributary 1.190. All data were collected in 2008 unless otherwise noted.

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.
[c] Data were recorded in 2004.

Table B.3-6.
Special habitat features within NFK-C and tributary 1.190, surveyed in 2008. Special features were documented in the field; there are known tributaries that were not documented during the 2008 surveys, including tributaries that were dry, obscured by vegetation, or not connected at the time of the survey.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.4
NORTH FORK KOKTULI RIVER REACH D (NFK-D)

Table B.4-1.
List of species found in NFK-D.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
northern pike	*Esox lucius*
ninespine stickleback	*Pungitius pungitius*
threespine stickleback	*Gasterosteus aculeatus*

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.4-2.
2004-2008 number of fish observations by lifestage within NFK-D mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

			Adult							Juvenile								Juvenile/Adult[a]					
Species	Year	Method	May	Jun	Jul	Aug	Sep	Oct	Sub-total	Apr	May	Jun	Jul	Aug	Sep	Oct	Sub-total	Apr	Jul	Aug	Sep	Sub-total	Total
Chinook salmon	2004	Electrofishing												4			4						4

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.6
NORTH FORK KOKTULI RIVER REACH F (NFK-F)

Table B.6-1.
List of species found in NFK-F.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
Dolly Varden	*Salvelinus malma*
sculpin [a]	*Cottus* sp.

[a] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.6-2.
2004-2008 number of fish observations by lifestage within NFK-F mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

Species	Year	Method	Adult			Juvenile				Juvenile/Adult[a]			Total
			Jul	Aug	Subtotal	Jul	Aug	Sep	Subtotal	Aug	Sep	Subtotal	
Chinook salmon	2008	Snorkel					4		4				4
Dolly Varden	2008	Electrofishing						4	4		1	1	5
		Snorkel								2		2	2
		Visual Observation		1	1						1	1	2
sculpin sp.	2005	Electrofishing	2		2	31			31				33
	2008	Electrofishing								29	14	43	43
		Snorkel								5		5	5

[a] This lifestage category includes subadult fish and fish whose lifestage was not, or could not, be determined.
Note: Blank cells indicate no data were collected for that record.

REACH ANALYSIS

SECTION B.7
SOUTH FORK KOKTULI RIVER REACH A (SFK-A)

Table B.7-1.
List of species found in SFK-A.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
Coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*
threespine stickleback	*Gasterosteus aculeatus*
lamprey [c]	*Lampetra* sp.

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

[c] identified to genus, may include arctic and Pacific lamprey

Table B.7-2.
2004-2008 number of fish observations by lifestage within SFK-A mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

Species	Year	Method	Adult					Juvenile						Juvenile/Adult[a]					Total
			Apr	Jul	Aug	Sep	Subtotal	Apr	Jul	Aug	Sep	Nov	Subtotal	Apr	Jul	Aug	Sep	Subtotal

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.8
SOUTH FORK KOKTULI RIVER REACH B (SFK-B)

Table B.8-1.
List of species found in SFK-B.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
burbot	*Lota lota*
northern pike	*Esox lucius*
ninespine stickleback	*Pungitius pungitius*
threespine stickleback	*Gasterosteus aculeatus*
lamprey [c]	*Lampetra* sp.

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

[c] identified to genus, may include arctic and Pacific lamprey

Table B.8-2.
Channel morphology data from areas sampled within SFK-B tributary 1.190.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)	Average Wetted Width (m)	Average Bankfull Width (m)	Maximum Bankfull Depth (m)
SFK 1.190-SA1	7/2/08	narrow low-gradient floodplain channel	3.0	8.0	10.3	0.9
SFK 1.190-SA2	6/24/04	narrow shallow contained channel	2.1	4.4	6.1	0.7
SFK 1.190-SA2	7/8/08	narrow mixed control channel	3.4	5.9	7.7	0.8

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

Table B.8-3.
Percent composition of primary habitat types from areas sampled within SFK-B tributary 1.190. All data were collected in 2008 unless otherwise noted.

Sample Area (SA)	Length (m)	Average Wetted Width (m)[a]	Total Wetted Area (m^2)[a]	Side Channel (% of Total Wetted Area)	Distributary (% of Total Wetted Area)	Primary Habitat Types (% survey length) / (% wetted area)[b,c,d]

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.
[c] Data were recorded in 2004.

Table B.8-6.
Special habitat features within SFK-B tributary 1.190, surveyed in 2008. Special features were documented in the field; there are known tributaries that were not documented during the 2008 surveys, including tributaries that were dry, obscured by vegetation, or not connected at the time of the survey.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.9
SOUTH FORK KOKTULI RIVER REACH C (SFK-C)

Table B.9-1.
List of species found in SFK-C.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
whitefish [a]	*Coregoninae*
burbot	*Lota lota*
northern pike	*Esox lucius*
sculpin [b]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*
stickleback [c]	*Gasterosteidae*

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

[c] identified to family, may include ninespine and threespine stickleback

Table B.9-2.
Channel morphology data from areas sampled within SFK-C and tributaries 1.240 and 1.260.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)[d]	Average Wetted Width (m)[d]	Average Bankfull Width (m)[d]	Maximum Bankfull Depth (m)[d]

[a] Dry and obscured habitat units were not included in Average Wetted Width, Total Wetted Area or Percent Wetted Area calculations.

[b] Pond, wetland, dry and obscured habitat types were included in 2008 sampling only.

[c] NA=data not available.

[d] Data were recorded in 2005.

[e] Data were recorded in 2004.

[f] SFK 1.240-SA3/4 (2004) was 30% SA3 and 70% SA4.

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.
[c] Data were recorded in 2005.
[d] Data were recorded in 2004.
[e] SFK 1.240-SA3/4 (2004) was comprised of 30% SA3 and 70% SA4.

Table B.9-6.
Special habitat features within SFK-C tributaries 1.240 and 1.260, surveyed in 2008. Special features were documented in the field; there are known tributaries that were not documented during the 2008 surveys, including tributaries that were dry, obscured by vegetation, or not connected at the time of the survey.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.10
SOUTH FORK KOKTULI RIVER REACH D (SFK-D)

Table B.10-1.
List of species found in SFK-D.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
coho salmon	*Oncorhynchus kisutch*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
northern pike	*Esox lucius*
sculpin [a]	*Cottus* sp.

[a] Identified to genus, may include slimy sculpin and coastrange sculpin

Table B.10-2.
Channel morphology data from areas sampled within SFK-D.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)[d]	Average Wetted Width (m)	Average Bankfull Width (m)[d]	Maximum Bankfull Depth (m)[d]
SFK-D-SA1	7/11/04	narrow shallow contained channel	NA	7.3	NA	NA
SFK-D-SA2[e]	7/12/04	narrow shallow contained channel	NA	6.9	NA	NA
SFK-D-SA3	7/12/04	narrow shallow contained channel	0.5	10.9	11.9	0.4
2004 SFK-D TOTAL			0.5	7.9	11.9	0.4

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

[d] NA=data not available.

[e] Sample Area was comprised of 51% narrow shallow contained channel and 49% beaver dam/pond channel.

Table B.10-3.
Percent composition of primary habitat types from areas sampled within SFK-D in 2004.

Sample Area (SA)	Length (m)	Average Wetted Width (m)[a]	Total Wetted Area (m^2)[a]	Side Channel (% of Total Wetted Area)	Distributary (% of Total Wetted Area)	Primary Habitat Types (% survey length) / (% wetted area)[b,c]									
						Backwater/ Slough	Beaver Complex	Cascade	Dry[a]	Obscured[a]	Pond/Lake	Pool	Riffle	Run/Glide	Wetland
SFK-D-SA1	352.4	7.3	2572.5	0	0	0 / 0	0 / 0	0 / 0	NA	NA	NA	0 / 0	2 / 2	98 / 98	NA
SFK-D-SA2	773.3	6.9	5322.0	0	0	0 / 0	49 / 49	0 / 0	NA	NA	NA	0 / 0	11 / 11	40 / 40	NA
SFK-D-SA3	737.3	10.9	8036.6	11	0	0 / 0	0 / 0	0 / 0	NA	NA	NA	0 / 0	91 / 91	8 / 8	NA
2004 SFK-D TOTAL	1863.0	7.9	15931.1	6	0	0 / 0	21 / 17	0 / 0	NA	NA	NA	0 / 0	39 / 48	40 / 35	NA

[a] Dry and obscured habitat units were not included in Average Wetted Width, Total Wetted Area or Percent Wetted Area calculations.

[b] Pond, wetland, dry and obscured habitat types were included in 2008 sampling only.

[c] NA=data not available.

Table B.10-4.
Descriptive characteristics of primary habitat units from areas sampled within SFK-D in 2004.

Sample Area (SA)	Dominant Substrate[a]	Subdominant Substrate[a]	Eroding Bank (% of Length)[a]	Undercut Bank (% of Length)	Dominant Riparian Vegetation[a]
SFK-D-SA1	NA	NA	NA	0	NA
SFK-D-SA2	NA	NA	NA	0	NA
SFK-D-SA3	gravel	NA	NA	0	alder shrub/willow shrub
2004 SFK-D TOTAL	gravel	NA	NA	0	alder shrub/willow shrub

[a] NA=data not available.

Table B.10-5.
Summary of 2004 pool habitat data from areas sampled in SFK-D.

Sample Area (SA)	Length (km)	Number of Pools			Pool Frequency (# pools/100m)			Pool Area (m^2)			Average Pool Area (m^2)	Average Residual Pool Depth (m)	Number of Holding Pools (≥1m deep; #/100m)
		Pri-mary[a]	Second-ary[b]	Total	Pri-mary	Second-ary	Total	Pri-mary	Second-ary	Total			
SFK-D-SA1	0.35	0	7	7	0	2.0	2.0	0	317.7	317.7	45.4	0.6	0.9
SFK-D-SA2	0.77	0	9	9	0	1.2	1.2	0	495.4	495.4	55.0	0.6	0.5
SFK-D-SA3	0.74	0	1	1	0	0.1	0.1	0	45.0	45.0	45.0	0.4	0
2004 SFK-D Total	1.86	0	17	17	0	0.9	0.9	0	858.1	858.1	50.5	0.6	0.4

[a] A primary pool was defined as one that occupies 50% or more of the channel width.
[b] A secondary pool was defined as one that occupies <50% of the channel width.

Table B.10-6.
2004-2008 number of fish observations by lifestage within SFK-D mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

			Adult				Juvenile				Juvenile/Adult[a]		
Species	Year	Method	May	Jul	Aug	Subtotal	Jul	Aug	Oct	Subtotal	Jul	Subtotal	Total
Chinook salmon	2008	Snorkel						3		3			3
coho salmon	2004	Electrofishing					35			35			35
	2008	Snorkel						4		4			4
arctic grayling	2004	Electrofishing		1		1	222			222	7	7	230
		Visual Observation									3	3	3
	2005	Angling	7			7							7
	2006	Electrofishing							1	1			1
	2007	Angling	1			1							1
	2008	Seine						17		17			17
		Snorkel						3		3			3
Dolly Varden	2008	Snorkel						12		12			12
Salmonid sp.	2008	Snorkel						5		5			5
northern pike	2004	Electrofishing					13			13			13
		Visual Observation					15			15			15
	2007	Angling	1			1							1
	2008	Snorkel						1		1			1
sculpin sp.	2004	Electrofishing									109	109	109
	2008	Seine			1	1		1		1			2

[a] This lifestage category includes subadult fish and fish whose lifestage was not, or could not, be determined.

Note: Blank cells indicate no data were collected for that record.

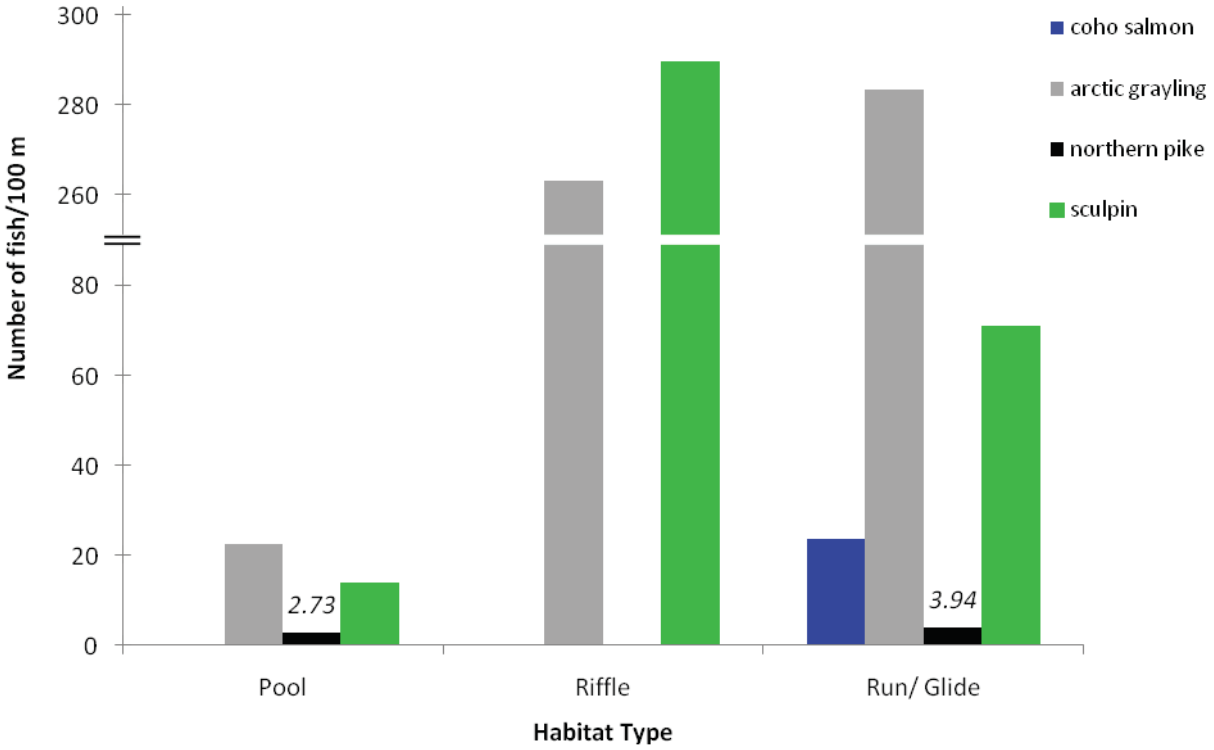

Figure B.10-8.
2004-2007 fish abundance by habitat type within mainstem SFK-D.

Table B.10-7.
SFK-D fish observation data collected during winter sampling, 2004-2007.

Observation Date	Site	Species	Method	Sample Length (m)	Juveniles	Total Fish Count	Fish Abundance (number/100 m)
10/31/2006	SFK-06-WT2	arctic grayling	electrofishing	30	1	1	3.3

Table B.10-8.
2008 fish observations by method at mainstem index sites located within SFK-D.

Index Site	Species	Method	Adult	Juvenile	Total
SFK51.96	Chinook salmon	snorkel		3	3
	coho salmon	snorkel		4	4
	arctic grayling	beach seine		17	17
		snorkel		3	3
	Dolly Varden	snorkel		12	12
	Salmonid sp.	snorkel		5	5
	northern pike	snorkel		1	1
	sculpin sp.	beach seine	1	1	2
SFK51.96 Total			**1**	**46**	**47**

Note: Blank cells indicate no data were collected for that record.

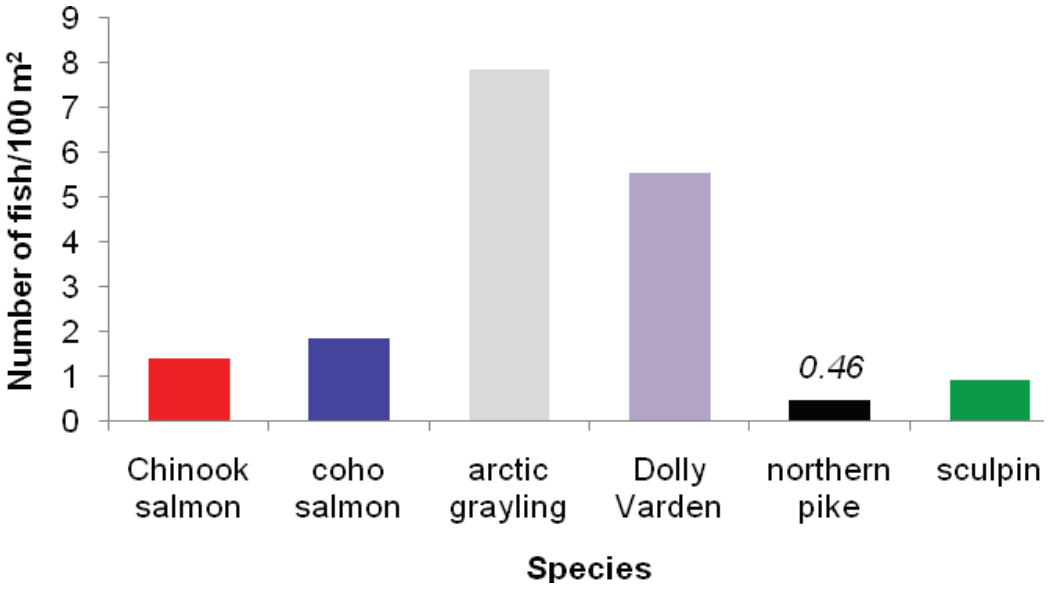

Figure B.10-10.
2008 fish density in pool habitat at mainstem index site (RKm 51.96) within SFK-D. Densities were calculated from the method that generated the greatest count of fish at this location.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.11
SOUTH FORK KOKTULI RIVER REACH E (SFK-E)

Table B.11-1.
List of species found in SFK-E.

Common Name	Scientific Name
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
northern pike	*Esox lucius*
sculpin [a]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*
threespine stickleback	*Gasterosteus aculeatus*

[a] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.11-2.
Channel morphology data from areas sampled within SFK-E and tributaries 1.310, 1.330, 1.340, 1.350, 1.360, 1.370, 1.400 and 1.440.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)[d]	Average Wetted Width (m)[d]	Average Bankfull Width (m)[d]	Maximum Bankfull Depth (m)[d]
SFK-E-SA1	8/13/08	narrow placid flow channel	1.3	6.3	7.8	0.9
SFK-E-SA2	8/15/08	narrow placid flow channel	1.5	5.5	6.8	0.7
SFK-E-SA3	8/15/08	narrow placid flow channel	1.5	3.3	4.2	0.7
SFK-E-SA4	8/16/08	narrow placid flow channel	1.3	1.6	3.1	0.7
SFK-E-SA5	8/17/08	narrow low-gradient floodplain channel	2.8	1.5	2.5	0.6
SFK-E REACH TOTAL			1.8	3.5	4.7	0.7
SFK 1.310-SA1	6/28/08	beaver dam/pond channel	1.7	33.8	44.2	1.5

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

[d] NA=data not available.

[e] SFK 1.310-SA7/8 (2004) was comprised of 75% SA7 and 25% SA8.

[f] SFK 1.330-SA2/3 (2004) was comprised of 70% SA2 and 30% SA3.

[g] Sample Area was comprised of 63% narrow placid flow channel and 37% beaver dam/pond channel.

Table B.11-3.
Percent composition of primary habitat types from areas sampled within SFK-E and tributaries 1.310, 1.320, 1.330, 1.340, 1.350, 1.360, 1.370, 1.380, 1.400, and 1.440. All data were collected in 2008 unless otherwise noted.

[a] Dry and obscured habitat units were not included in Average Wetted Width, Total Wetted Area or Percent Wetted Area calculations.

[b] Pond, wetland, dry and obscured habitat types were included in 2008 sampling only.

[c] NA=data not available.

[d] Data were recorded in 2004.

[e] SFK 1.310-SA7/8 (2004) was 75% of SA7 and 25% of SA8.

[f] SFK 1.330-SA2/3 (2004) was 70% of SA2, and 30% of SA3.

Table B.11-4.

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.
[c] Data were recorded in 2004.
[d] SFK 1.310-SA7/8(2004) was comprised of 75% SA7 and 25% SA8.
[e] SFK 1.330-SA2/3(2004) was comprised of 70% SA2 and 30% SA3.

Table B.11-6.
Special habitat features within SFK-E and tributaries 1.310, 1.320, 1.330, 1.340, 1.350, 1.360, 1.370, 1.380, 1.400, and 1.440, surveyed in 2008. Special features were documented in the field; there are known tributaries that were not documented during the 2008 surveys, including tributaries that were dry, obscured by vegetation, or not connected at the time of the survey.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.12
UPPER TALARIK CREEK RIVER REACH A (UT-A)

Table B.12-1.
List of species found in UT-A.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
Chum salmon	*Oncorhynchus keta*
Coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
rainbow trout	*Oncorhynchus mykiss*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
stickleback [c]	*Gasterosteidae*

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

[c] identified to family, may include ninespine and threespine stickleback

Table B.12-2.
Channel morphology data from areas sampled within UT-A.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)	Average Wetted Width (m)	Average Bankfull Width (m)	Maximum Bankfull Depth (m)
UT-A-SA1 / TOTAL	9/7/08	low-gradient floodplain channel	1.4	18.0	30.3	1.4

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

Table B.12-3.
Percent composition of primary habitat types from areas sampled within UT-A in 2008.

Sample Area (SA)	Length (m)	Average Wetted Width (m)[a]	Total Wetted Area (m^2)[a]	Side Channel (% of Total Wetted Area)	Distributary (% of Total Wetted Area)	Primary Habitat Types (% survey length) / (% wetted area)									
						Backwater/ Slough	Beaver Complex	Cascade	Dry[a]	Obscured[a]	Pond/Lake	Pool	Riffle	Run/Glide	Wetland
UT-A-SA1 / TOTAL	11943.8	14.2	169530.0	16	0	6 / 4	0 / 0	0 / 0	0	0	0 / 0	9 / 13	55 / 62	30 / 22	0 / 0

[a]Dry and obscured habitat units were not included in Average Wetted Width, Total Wetted Area or Percent Wetted Area calculations.

Table B.12-4.
Descriptive characteristics of primary habitat units from areas sampled within UT-A in 2008.

Sample Area (SA)	Dominant Substrate	Subdominant Substrate	Eroding Bank (% of Length)	Undercut Bank (% of Length)[a]	Dominant Riparian Vegetation
UT-A-SA1 / TOTAL	gravel	sand/silt	0	NA	willow shrub

[a] NA=data not available.

Table B.12-5.
Summary of 2008 pool habitat data from areas sampled in UT-A.

Sample Area (SA)	Length (km)	Number of Pools			Pool Frequency (# pools/100m)			Pool Area (m^2)			Average Pool Area (m^2)	Average Residual Pool Depth (m)	Number of Holding Pools (≥1m deep; #/100m)
		Pri-mary[a]	Second-ary[b]	Total	Pri-mary	Second-ary	Total	Pri-mary	Second-ary	Total			
UT-A-SA1 /TOTAL	11.94	32	0	32	0.3	0	0.3	22236.8	0	22236.8	694.9	0.9	0.3

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.

Table B.12-6.
Special habitat features within UT-A, surveyed in 2008. Special features were documented in the field; there are known tributaries that were not documented during the 2008 surveys, including tributaries that were dry, obscured by vegetation, or not connected at the time of the survey.

Sample Area (SA)	Feature Location		Feature Type	Tributary Stream Code	Barrier Characteristics			
	Latitude (WGS84)	Longitude (WGS84)			Type	Status	Height (m)	Length (m)
UT-A-SA1	59.68118	-155.22060	tributary	UT 1.60				
	59.67698	-155.22267	spring					
	59.66582	-155.21210	spring					

Note: Blank cells indicate no data were collected for that record.

Table B.12-7.
2004-2008 number of fish observations by lifestage within UT-A mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

Species	Year	Method	Adult					Juvenile			Juvenile/Adult[a]					Total
			May	Jun	Aug	Sep	Subtotal	Aug	Sep	Subtotal	May	Jun	Aug	Sep	Subtotal	
Chinook salmon	2008	Snorkel							63	63						63
coho salmon	2004	Visual Observation			601		601			0						601
	2008	Snorkel				72	72		771	771						843
sockeye salmon	2008	Seine			1		1									1
		Snorkel			5	7	12		26	26						38
arctic grayling	2008	Angling		15			15									15
		Snorkel							3	3				1	1	4
rainbow trout	2007	Angling			23	13	36									36
	2008	Angling	20	68			88				1	1			2	90
		Seine						1		1						1
		Snorkel				4	4		316	316				3	3	323
whitefish sp.	2008	Angling		1			1									1
sculpin sp.	2008	Seine			1		1	9		9						10
		Snorkel											5	17	22	22
stickleback sp.	2008	Seine			27		27	22		22						49
		Snorkel											241	549	790	790

[a] This lifestage category includes subadult fish and fish whose lifestage was not, or could not, be determined.

Note: Blank cells indicate no data were collected for that record.

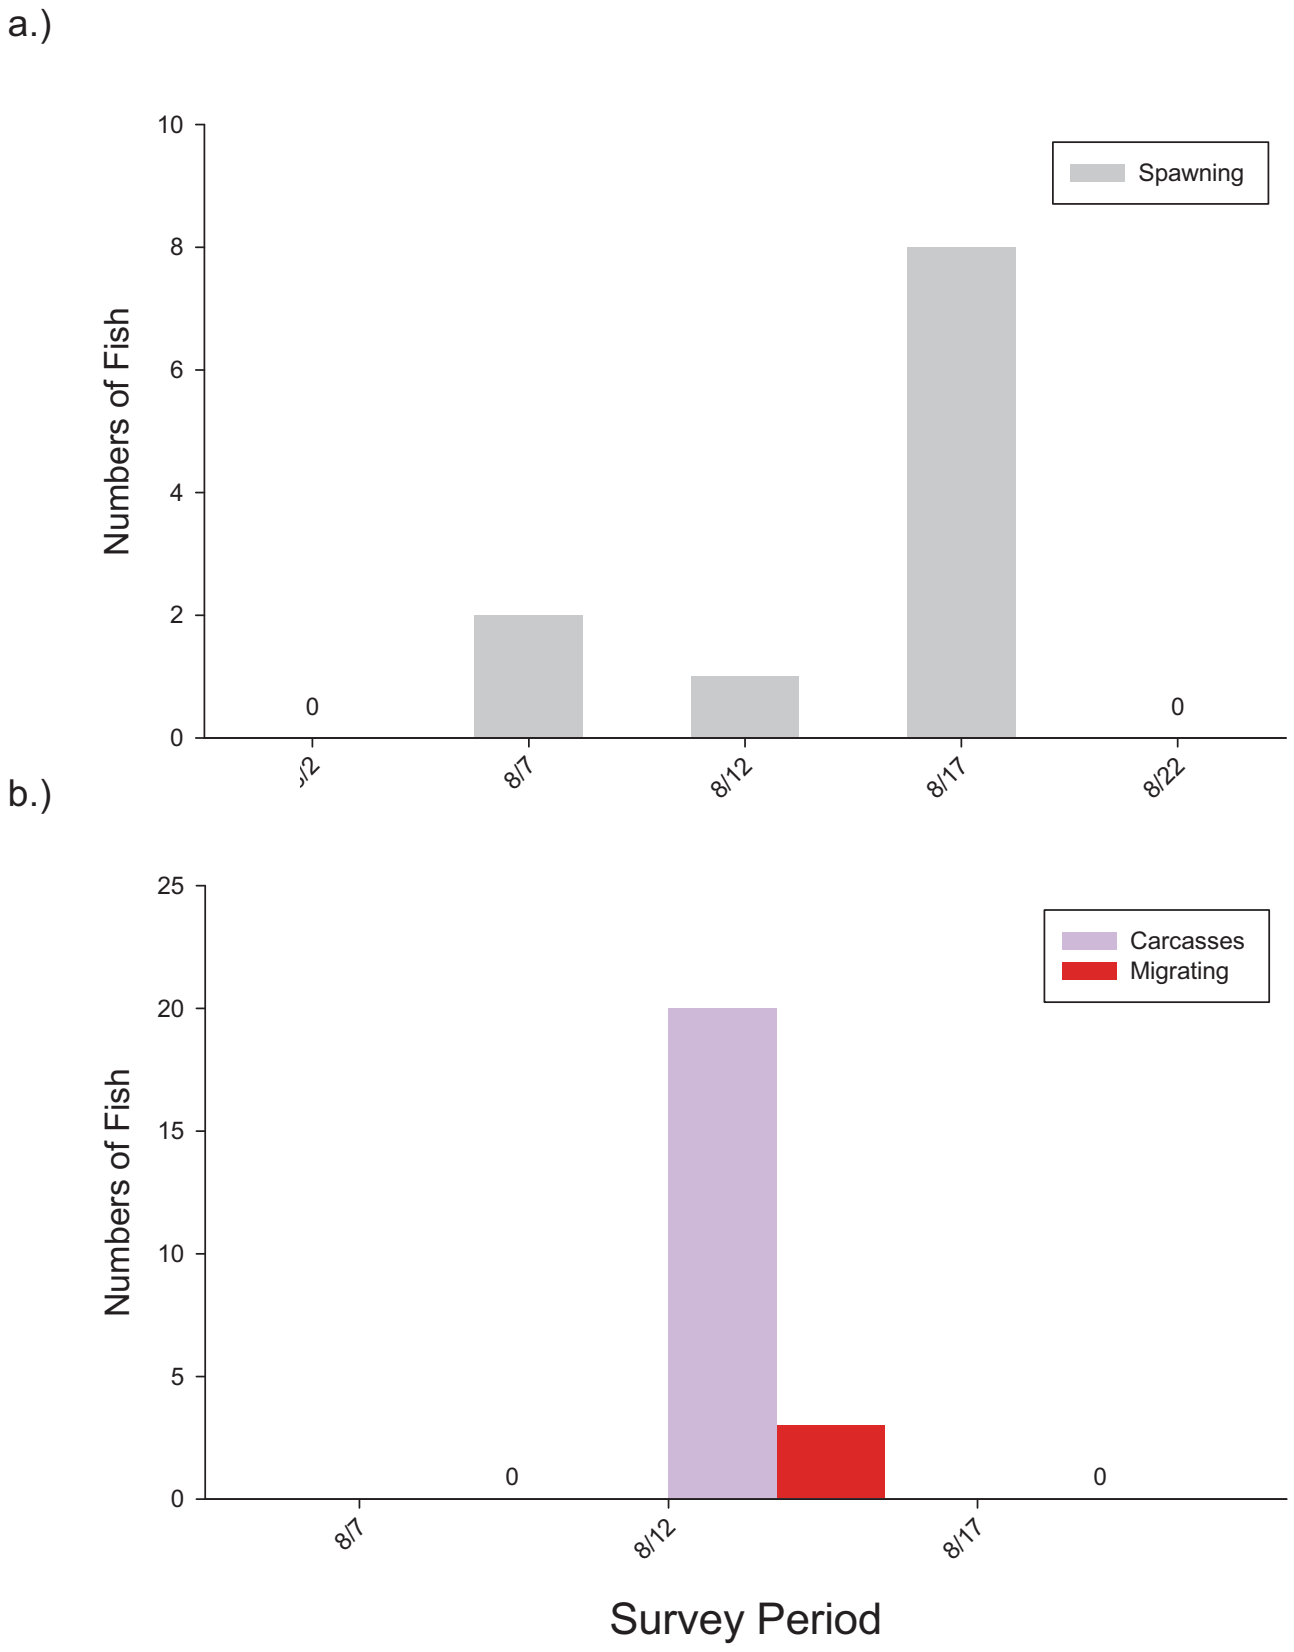

Figure B.12-12.
Observations of Chinook salmon during 2008 aerial surveys in UT-A. a.) Number of Chinook salmon spawning. b.) Number of Chinook salmon observed in spawning related behaviors.

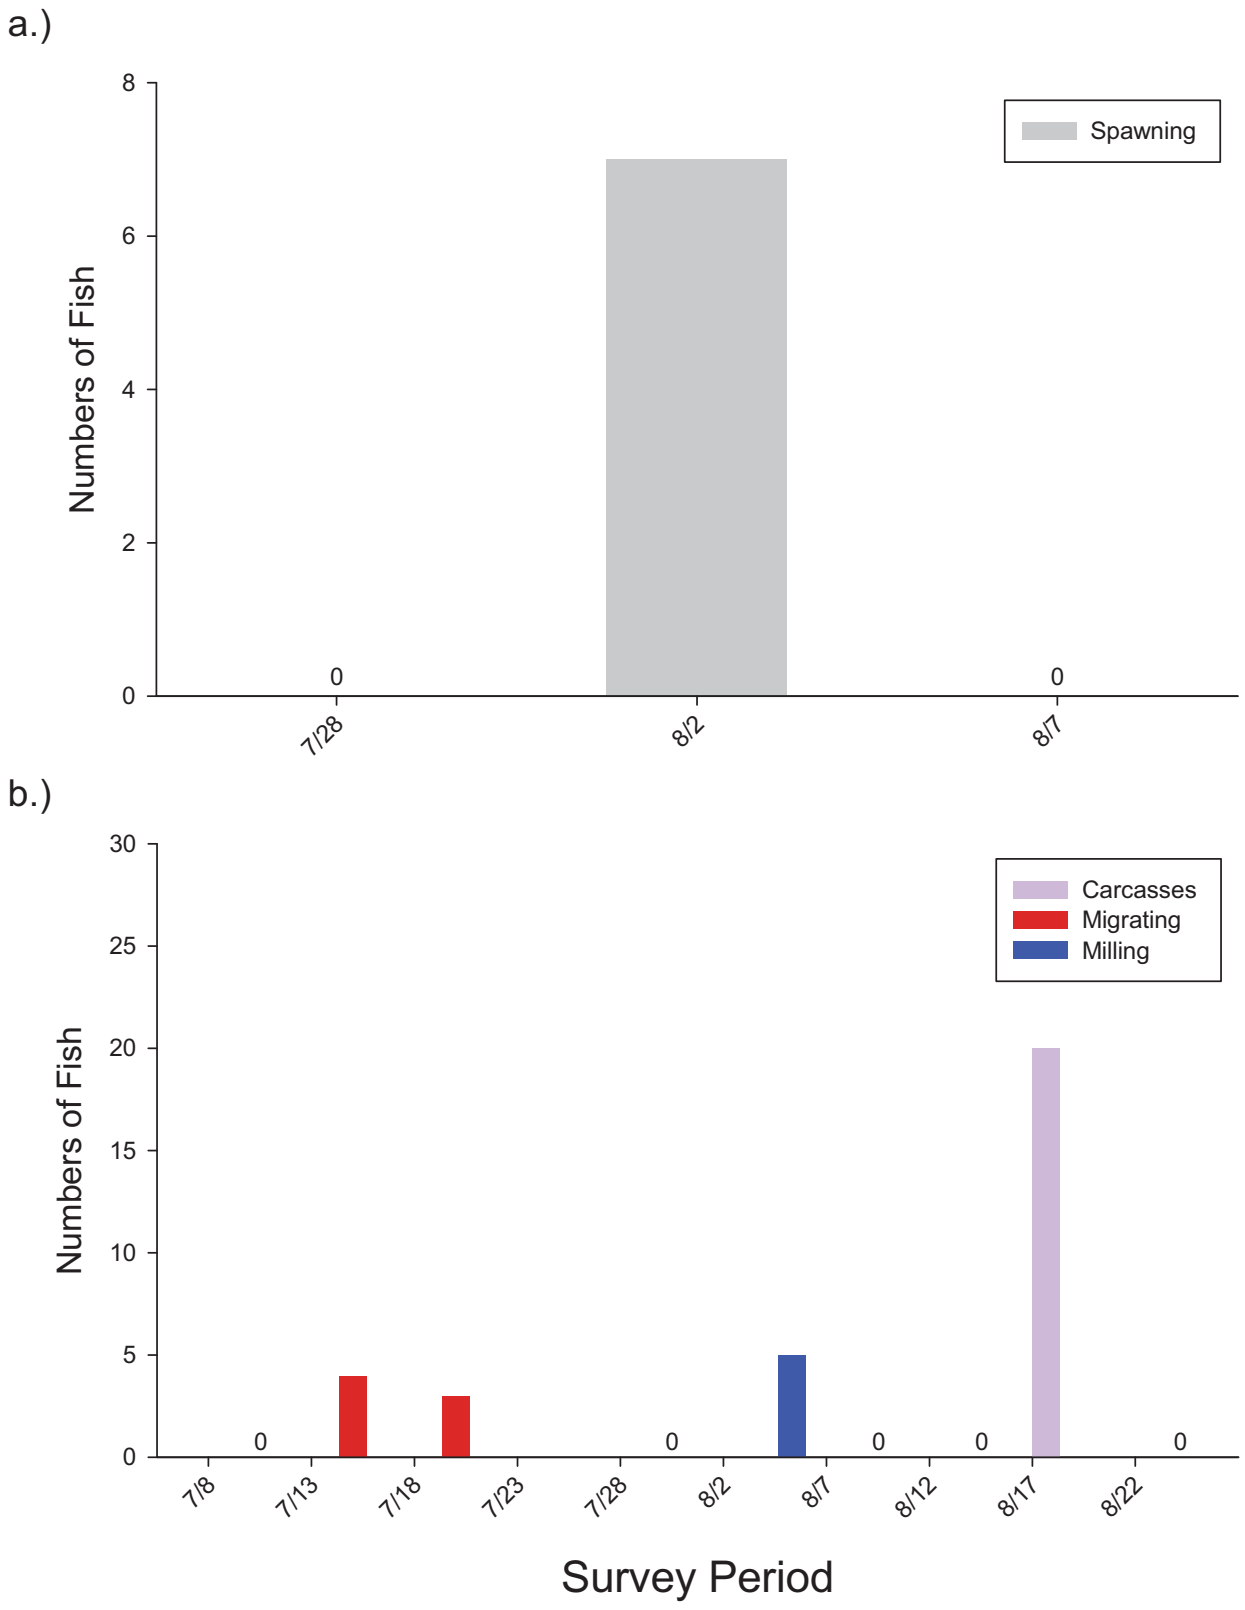

Figure B.12-13.
Observations of chum salmon during 2008 aerial surveys in UT-A. a.) Number of chum salmon spawning and b.) Number of chum salmon observed in spawning related behaviors.

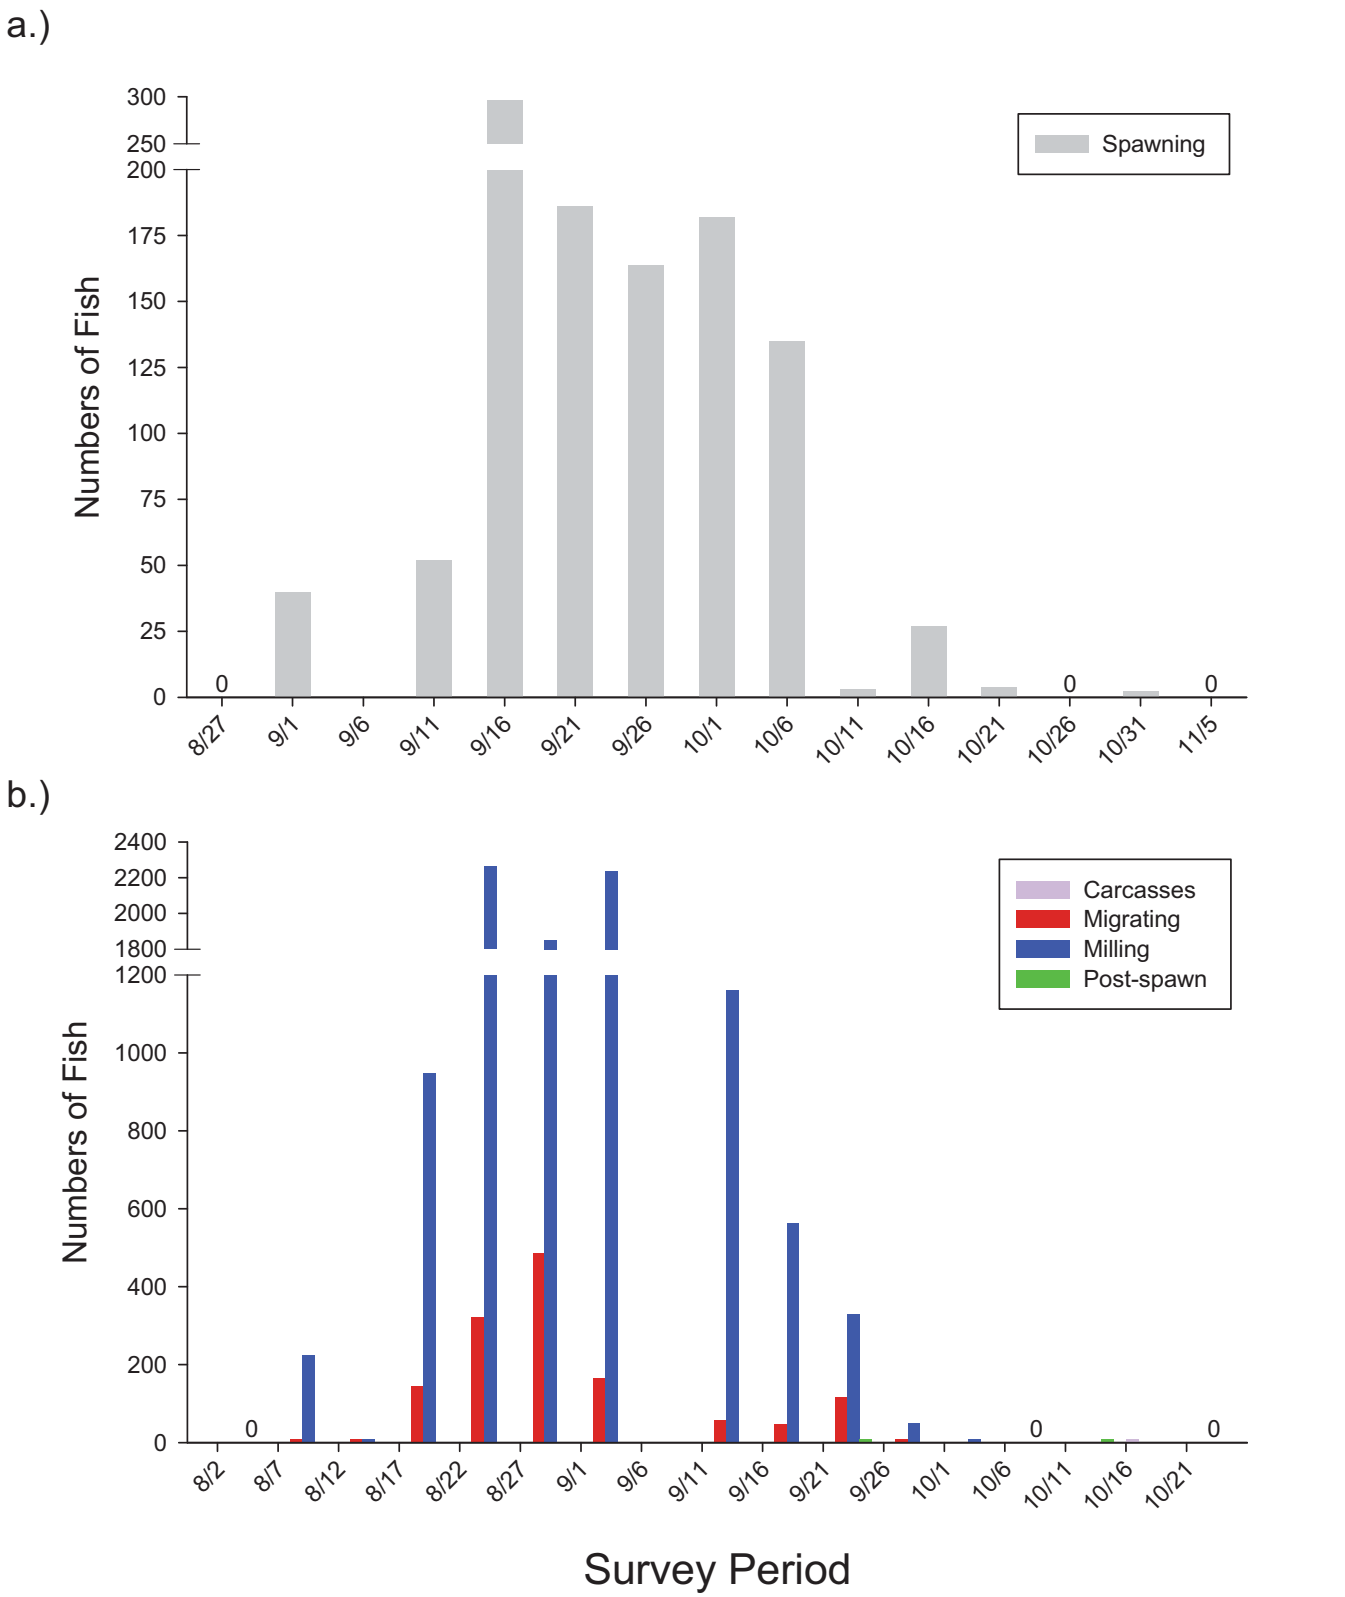

Figure B.12-14.
Observations of coho salmon during 2008 aerial surveys in UT-A. a.) Number of coho salmon spawning and b.) Number of coho salmon observed in spawning related behaviors.

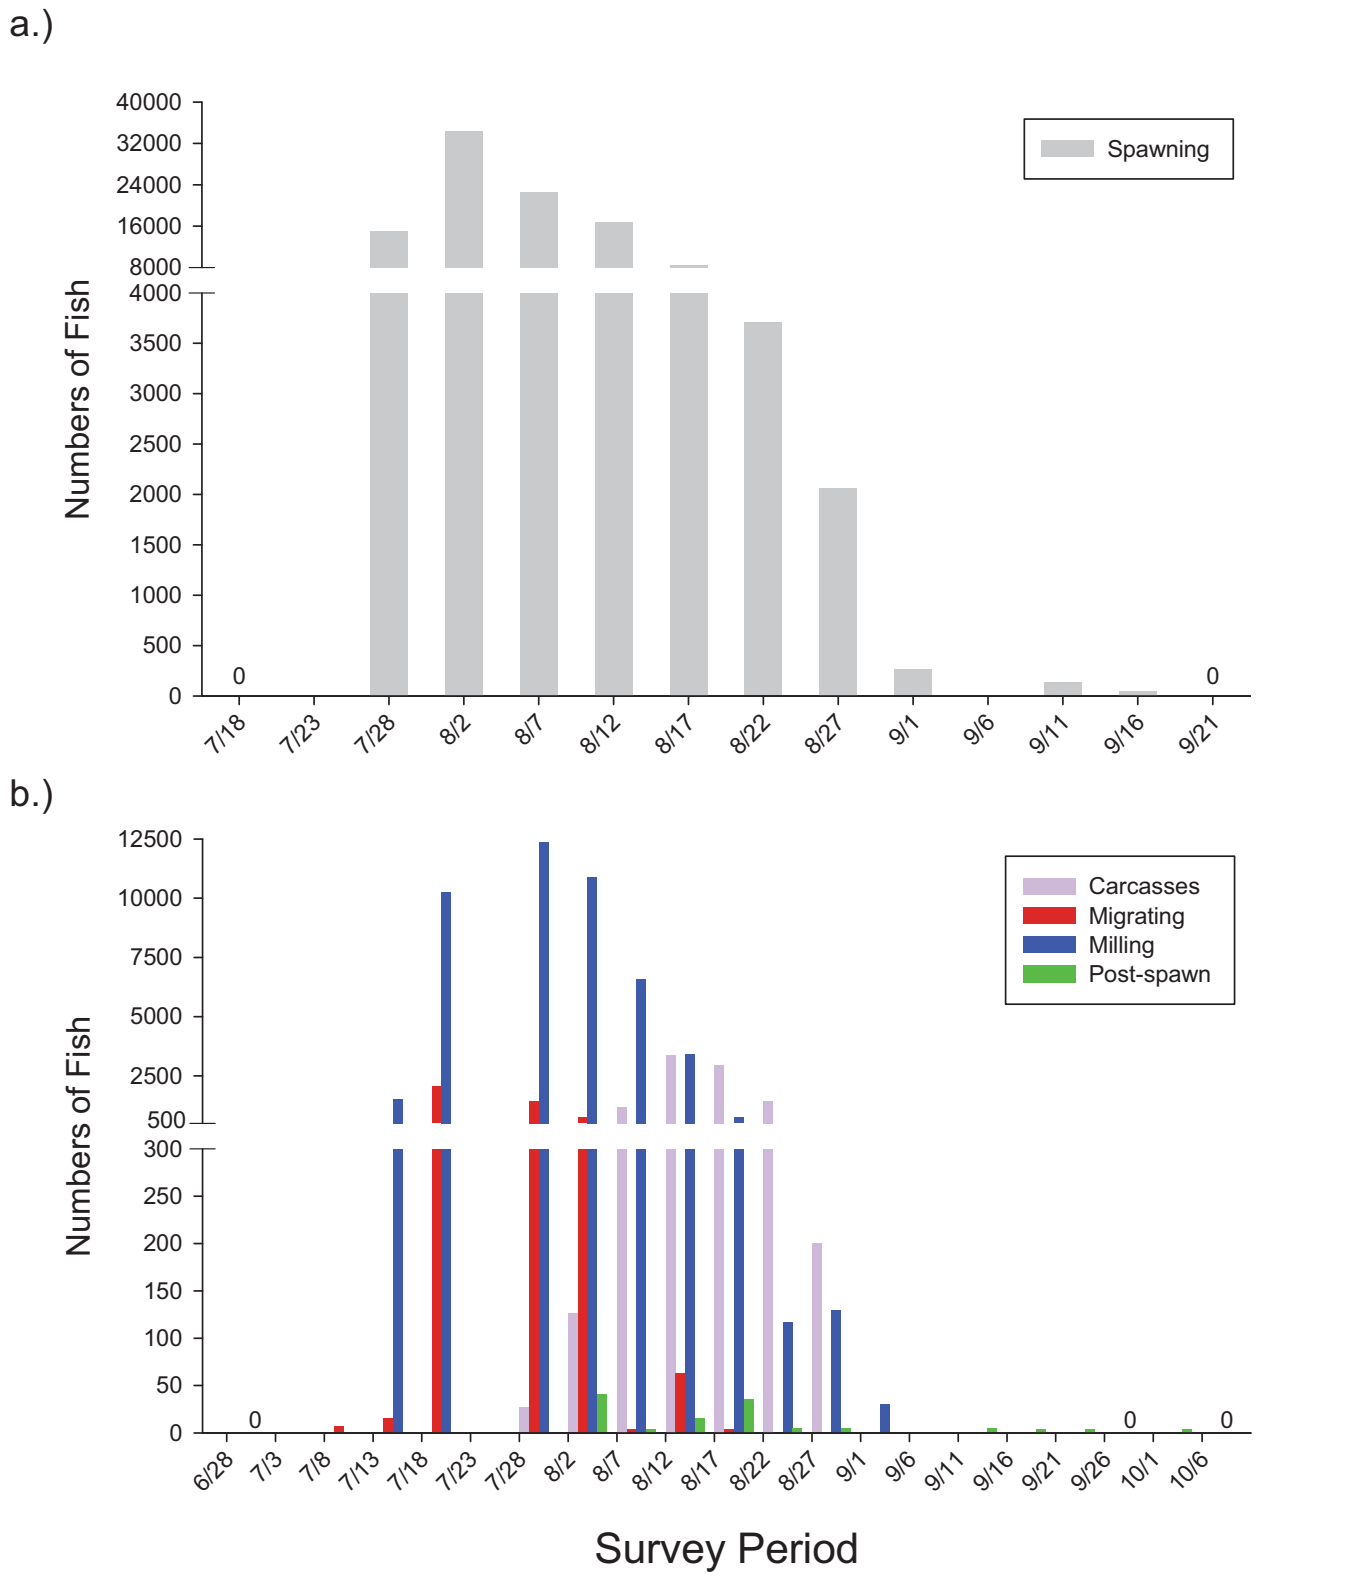

Figure B.12-15.
Observations of sockeye salmon during 2008 aerial surveys in UT-A. a.) Number of sockeye salmon spawning. b.) Number of sockeye salmon observed in spawning related behaviors.

Table B.12-8.
2008 fish observations by method at mainstem index sites located within UT-A.

Index Site	Species	Method	Adult	Juvenile	Juvenile/ Adult[a]	Total
UTC00.0	sockeye salmon	beach seine	1			1
	sculpin sp.	beach seine	1	8		9
		snorkel			3	3
	stickleback sp.	beach seine	27	22		49
		snorkel			241	241
UTC00.0 Total			**29**	**30**	**244**	**303**
UTC04.33	sockeye salmon	snorkel	5			5
	rainbow trout	beach seine		1		1
	sculpin sp.	beach seine		1		1
		snorkel			2	2
UTC04.33 Total			**5**	**2**	**2**	**9**

[a] This lifestage category includes subadult fish and fish whose lifestage was not, or could not, be determined.

Note: Blank cells indicate no data were collected for that record.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.13
UPPER TALARIK CREEK RIVER REACH B (UT-B)

Table B.13-1.
List of species found in UT-B.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
sculpin [a]	*Cottus* sp.
stickleback [b]	*Gasterosteidae*

[a] identified to genus, may include slimy sculpin and coastrange sculpin

[b] identified to family, may include ninespine and threespine stickleback

Table B.13-2.
Channel morphology data from areas sampled within UT-B.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)	Average Wetted Width (m)	Average Bankfull Width (m)	Maximum Bankfull Depth (m)
UT-B-SA1 / TOTAL	9/5/08	low-gradient floodplain channel	1.2	16.1	26.8	1.4

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

Table B.13-3.
Percent composition of primary habitat types from areas sampled within UT-B in 2008.

Sample Area (SA)	Length (m)	Average Wetted Width (m)[a]	Total Wetted Area (m^2)[a]	Side Channel (% of Total Wetted Area)	Distributary (% of Total Wetted Area)	Primary Habitat Types (% survey length) / (% wetted area)									
						Backwater/ Slough	Beaver Complex	Cascade	Dry[a]	Obscured[a]	Pond/Lake	Pool	Riffle	Run/Glide	Wetland
UT-B-SA1 / TOTAL	14973.1	15.2	226558.8	20	0	6 / 2	7 / 11	0 / 0	0	0	0 / 0	5 / 4	60 / 68	22 / 14	0 / 0

[a] Dry and obscured habitat units were not included in Average Wetted Width, Total Wetted Area or Percent Wetted Area calculations.

Table B.13-4.
Descriptive characteristics of primary habitat units from areas sampled within UT-B in 2008.

Sample Area (SA)	Dominant Substrate	Subdominant Substrate	Eroding Bank (% of Length)	Dominant Riparian Vegetation
UT-B-SA1 / TOTAL	gravel	sand/silt	0	willow shrub

Table B.13-5.
Summary of 2008 pool habitat data from areas sampled in UT-B.

Sample Area (SA)	Length	Number of Pools			Pool Frequency (# pools/100m)			Pool Area (m^2)			Average Pool Area (m^2)	Average Residual Pool Depth (m)	Number of Holding Pools (≥1m deep; #/100m)
		Pri-mary[a]	Second-ary[b]	Total	Pri-mary	Second-ary	Total	Pri-mary	Second-ary	Total			
UT-B-SA1 / TOTAL	14.97	17	0	17	0.1	0	0.1	9169.7	0	9169.7	539.4	1.0	0.1

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.

Table B.13-6.
Special habitat features within UT-B, surveyed in 2008. Special features were documented in the field; there are known tributaries that were not documented during the 2008 surveys, including tributaries that were dry, obscured by vegetation, or not connected at the time of the survey.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.14
UPPER TALARIK CREEK RIVER REACH C (UT-C)

Table B.14-1.
List of species found in UT-C.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*
threespine stickleback	*Gasterosteus aculeatus*

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.14-2.
Channel morphology data from areas sampled within UT-C tributary UT 1.190.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)	Average Wetted Width (m)[d]	Average Bankfull Width (m)[d]	Maximum Bankfull Depth (m)[d]
UT 1.190-SA1	6/23/04	narrow mixed control channel	3.0	NA	NA	NA
UT 1.190-SA2[e]	6/23/04	narrow shallow contained channel	8.3	NA	NA	NA
UT 1.190-SA3[f]	6/24/04	narrow shallow contained channel	1.0	NA	NA	NA
UT 1.190-SA4[g]	7/9/04	narrow shallow contained channel	2.5	NA	NA	NA
UT 1.190 TOTAL			4.6	NA	NA	NA

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

[d] NA=data not available.

[e] Sample Area was comprised of 96% narrow shallow contained channel and 4% deeply incised upper valley channel.

[f] Sample Area was comprised of 63% narrow shallow contained channel and 37% beaver dam/pond channel.

[g] Sample Area was comprised of 68% narrow shallow contained channel and 32% beaver dam/pond channel.

Table B.14-3.
Percent composition of primary habitat types from areas sampled within UT-C tributary 1.190 in 2004.

Sample Area (SA)	Length (m)	Average Wetted Width (m)[a,c]	Total Wetted Area (m^2)[a,c]	Side Channel (% of Total Wetted Area)[c]	Distributary (% of Total Wetted Area)	Primary Habitat Types (% survey length) / (% wetted area)[b,c]									
						Backwater/ Slough	Beaver Complex	Cascade	Dry[a]	Obscured[a]	Pond/Lake	Pool	Riffle	Run/Glide	Wetland
UT 1.190-SA1	683.0	NA	NA	NA	0	0 / NA	0 / NA	0 / NA	NA	NA	NA	0 / NA	100 / NA	0 / NA	NA
UT 1.190-SA2	2564.0	NA	NA	NA	0	0 / NA	0 / NA	4 / NA	NA	NA	NA	0 / NA	96 / NA	0 / NA	NA
UT 1.190-SA3	247.0	NA	NA	NA	0	0 / NA	37 / NA	0 / NA	NA	NA	NA	0 / NA	63 / NA	0 / NA	NA
UT 1.190-SA4	452.8	NA	NA	NA	0	0 / NA	9 / NA	0 / NA	NA	NA	NA	1 / NA	84 / NA	6 / NA	NA
UT 1.190 TOTAL	3946.8	NA	NA	NA	0	0 / NA	4 / NA	3 / NA	NA	NA	NA	0 / NA	93 / NA	1 / NA	NA

[a] Dry and obscured habitat units were not included in Average Wetted Width, Total Wetted Area or Percent Wetted Area calculations.

[b] Pond, wetland, dry and obscured habitat types were included in 2008 sampling only.

[c] NA=data not available.

Table B.14-4. Descriptive characteristics of primary habitat units from areas sampled within UT-C tributary 1.190 in 2004.

Sample Area (SA)	Dominant Substrate	Subdominant Substrate[a]	Eroding Bank (% of Length)[a]	Undercut Bank (% of Length)	Dominant Riparian Vegetation[a]
UT 1.190-SA1	cobble	organic	NA	4	NA
UT 1.190-SA2	cobble	bedrock	NA	13	NA
UT 1.190-SA3	gravel	organic	NA	5	NA
UT 1.190-SA4	gravel	NA	NA	1	NA
UT 1.190 TOTAL	cobble	gravel	NA	9	NA

[a] NA=data not available.

Table B.14-5.
Summary of 2004 pool habitat data from areas sampled within UT-C tributary 1.190.

Sample Area (SA)	Length (km)	Number of Pools			Pool Frequency (# pools/100m)			Pool Area (m^2)			Average Pool Area (m^2)	Average Residual Pool Depth (m)	Number of Holding Pools (≥1m deep; #/100m)
		Pri-mary[a]	Secon-dary[b]	Total	Pri-mary	Secon-dary	Total	Pri-mary	Secon-dary	Total			
UT 1.190-SA1	0.68	0	2	2	0	0.3	0.3	0	16.7	16.7	8.4	0.3	0
UT 1.190-SA2	2.56	0	13	13	0	0.5	0.5	0	106.7	106.7	8.2	0.7	0.1
UT 1.190-SA3	0.25	0	0	0	0	0	0	0	0	0	0	0	0
UT 1.190-SA4	0.45	1	8	9	0.2	1.8	2.0	25.7	131.7	157.4	17.5	0.6	0.4
UT 1.190 TOTAL	3.95	1	23	24	0	0.6	0.6	25.7	255.1	280.8	11.7	0.6	0.1

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.

Table B.14-6.
2004-2008 number of fish observations by lifestage within UT-C mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

			Adult				Juvenile						Juvenile/Adult[a]				
Species	Year	Method	Jun	Jul	Aug	Subtotal	Apr	Jun	Jul	Aug	Nov	Subtotal	Jun	Jul	Aug	Subtotal	Total

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.15
UPPER TALARIK CREEK RIVER REACH D (UT-D)

Table B.15-1.
List of species found in UT-D.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*
threespine stickleback	*Gasterosteus aculeatus*

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.15-2.
2004-2008 number of fish observations by lifestage within UT-D mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

			Adult						Juvenile							Juvenile/Adult[a]						
Species	Year	Method	Jul	Aug	Sep	Oct	Nov	Subtotal	Apr	Jun	Jul	Aug	Oct	Nov	Subtotal	Apr	Jun	Jul	Aug	Oct	Subtotal	Total
Chinook salmon	2005	Minnow Trap							2			28			30							30

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.16
UPPER TALARIK CREEK RIVER REACH E (UT-E)

Table B.16-1.
List of species found in UT-E.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
sculpin [a]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*
threespine stickleback	*Gasterosteus aculeatus*

[a] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.16-2.
Channel morphology data from areas sampled within UT-E tributary 1.310.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)[d]	Average Wetted Width (m)[d]	Average Bankfull Width (m)[d]	Maximum Bankfull Depth (m)[d]
UT 1.310-SA1[e]	6/20/04	narrow shallow contained channel	NA	NA	NA	NA
UT 1.310-SA2[f]	6/20/04	narrow shallow contained channel	NA	NA	NA	NA
UT 1.310-SA3	6/20/04	beaver dam/pond channel	NA	NA	NA	NA
UT 1.310-SA4	6/20/04	narrow shallow contained channel	2.5	NA	NA	NA
UT 1.310 TOTAL			2.5	NA	NA	NA

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

[d] NA=data not available.

[e] Sample Area was comprised of 81% narrow shallow contained channel and 19% beaver dam/pond channel.

[f] Sample Area was comprised of 83% narrow shallow contained channel and 17% beaver dam/pond channel.

Table B.16-3.
Percent composition of primary habitat types from areas sampled within UT-E tributary 1.310 in 2004.

Sample Area (SA)	Length (m)	Average Wetted Width (m)[a,c]	Total Wetted Area (m^2)[a,c]	Side Channel (% of Total Wetted Area)[c]	Distributary (% of Total Wetted Area)	Primary Habitat Types (% survey length) / (% wetted area)[b,c]									
						Backwater/ Slough	Beaver Complex	Cascade	Dry[a]	Obscured[a]	Pond/Lake	Pool	Riffle	Run/Glide	Wetland
UT 1.310-SA1	1265.8	NA	NA	NA	0	0 / NA	2 / NA	0 / NA	NA	NA	NA	2 / NA	77 / NA	20 / NA	NA
UT 1.310-SA2	644.6	NA	NA	NA	0	0 / NA	17 / NA	0 / NA	NA	NA	NA	1 / NA	76 / NA	6 / NA	NA
UT 1.310-SA3	595.9	NA	NA	NA	0	0 / NA	100 / NA	0 / NA	NA	NA	NA	0 / NA	0 / NA	0 / NA	NA
UT 1.310-SA4	776.7	NA	NA	NA	0	0 / NA	0 / NA	0 / NA	NA	NA	NA	0 / NA	99 / NA	1 / NA	NA
UT 1.310 TOTAL	3283.0	NA	NA	NA	0	0 / NA	22 / NA	0 / NA	NA	NA	NA	1 / NA	68 / NA	9 / NA	NA

[a] Dry and obscured habitat units were not included in Average Wetted Width, Total Wetted Area or Percent Wetted Area calculations.

[b] Pond, wetland, dry and obscured habitat types were included in 2008 sampling only.

[c] NA=data not available.

Table B.16-4.
Descriptive characteristics of primary habitat units from areas sampled within UT-E tributary 1.310 in 2004.

Sample Area (SA)	Dominant Substrate	Subdominant Substrate[a]	Eroding Bank (% of Length)[a]	Undercut Bank (% of Length)	Dominant Riparian Vegetation[a]
UT 1.310-SA1	gravel	organic, sand/silt	NA	4	alder shrub/willow shrub
UT 1.310-SA2	gravel	organic, sand/silt	NA	0	NA
UT 1.310-SA3	organic	NA	NA	0	NA
UT 1.310-SA4	gravel	NA	NA	0	NA
UT 1.310 TOTAL	gravel	organics	NA	1	alder shrub/willow shrub

[a] NA=data not available.

Table B.16-5.
Summary of 2004 pool habitat data from areas sampled in UT-E tributary 1.310.

Sample Area (SA)	Length (km)	Number of Pools			Pool Frequency (# pools/100m)			Pool Area (m^2)			Average Pool Area (m^2)	Average Residual Pool Depth (m)	Number of Holding Pools (≥1m deep; #/100m)
		Pri-mary[a]	Second-ary[b]	Total	Pri-mary	Second-ary	Total	Pri-mary	Second-ary	Total			
UT 1.310-SA1	1.27	2	39	41	0.2	3.1	3.2	82.7	519.4	602.2	14.7	0.4	0.2
UT 1.310-SA2	0.64	1	16	17	0.2	2.5	2.6	11.1	104.4	115.4	6.8	0.4	0
UT 1.310-SA3	0.60	0	0	0	0	0	0	0	0	0	0	0	0
UT 1.310-SA4	0.78	0	8	8	0	1.0	1.0	0	0	136.5	17.1	0.4	0
UT 1.310 TOTAL	3.28	3	63	66	0.1	1.9	2.0	93.8	760.3	854.2	12.9	0.4	0.1

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.

Table B.16-6.
2004-2008 number of fish observations by lifestage within UT-E mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

Species	Year	Method	Adult								Juvenile								Juvenile/Adult[a]							Total
			Apr	Jun	Jul	Aug	Sep	Oct	Nov	Subtotal	Apr	Jun	Jul	Aug	Sep	Oct	Nov	Subtotal	Apr	May	Jun	Jul	Aug	Oct	Subtotal	
Chinook salmon	2004	Electrofishing													2			2								2
	2005	Snorkel											36					36								36

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.17
UPPER TALARIK CREEK RIVER REACH F (UT-F)

Table B.17-1.
List of species found in UT-F.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
sculpin [a]	*Cottus* sp.
ninespine stickleback	*Pungitius pungitius*
stickleback [b]	*Gasterosteidae*

[a] identified to genus, may include slimy sculpin and coastrange sculpin

[b] identified to family, may include ninespine and threespine stickleback

Table B.17-2.
Channel morphology data from areas sampled within UT-F and tributaries 1.360, 1.370, 1.380, 1.390, 1.410, 1.420, 1.430, 1.440, 1.460, and 1.470.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)[d]	Average Wetted Width (m)[d]	Average Bankfull Width (m)[d]	Maximum Bankfull Depth (m)[d]
UT-F-SA1	6/22/05	narrow shallow contained channel	1.4	7.5	NA	NA

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

[d] NA=data not recorded.

[e] Sample Area was comprised of 88% narrow shallow contained channel and 12% beaver dam/pond channel.

[f] UT 1.380-SA1/2 (2007) was comprised of 18% SA1 and 82% SA2.

[g] UT 1.390-SA1/2 (2007) was comprised 71% SA1 and 29% SA2.

[h] UT 1.390-SA2/3/4 (2007) was comprised 5% SA2, 40% SA3, and 55% SA4.

Table B.17-3.
Percent composition of primary habitat types from areas sampled within UT-F and tributaries 1.360, 1.370, 1.380, 1.390, 1.400, 1.410, 1.420, 1.430, 1.440, 1.450, 1.460, and 1.470. All data were collected in 2008 unless otherwise noted.

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.
[c] Data were recorded in 2005.
[d] Data were recorded in 2004.
[e] Data were recorded in 2007.
[f] UT 1.380-SA1/2 (2007) was comprised of 18% SA1 and 82% SA2.
[g] UT 1.390-SA1/2 (2007) was comprised of 71% SA1 and 29% SA2.
[h] UT 1.390-SA2/3/4 (2007) was comprised of 5% SA2, 40% SA3, and 55% SA4.

Table B.17-6.
Special habitat features within UT-F tributaries 1.360, 1.370, 1.380, 1.390, 1.400, 1.410, 1.420, 1.430, 1.440, 1.450, 1.460, and 1.470, surveyed in 2008. Special features were documented in the field; there are known tributaries that were not documented during the 2008 surveys, including tributaries that were dry, obscured by vegetation, or not connected at the time of the survey.

CHAPTER 15, APPENDIX B
REACH ANALYSIS

SECTION B.18
UPPER TALARIK CREEK RIVER REACH G (UT-G)

Table B.18-1.
List of species found in UT-G.

Common Name	Scientific Name
coho salmon	*Oncorhynchus kisutch*
Dolly Varden	*Salvelinus malma*
sculpin [a]	*Cottus* sp.

[a] identified to genus, may include slimy sculpin and coastrange sculpin

Table B.18-2.
Channel morphology data from areas sampled within UT-G and tributaries 1.490 and 1.500.

Sample Area (SA)[a]	Survey Date[b]	USFS Channel Type[c]	Gradient (%)	Average Wetted Width (m)	Average Bankfull Width (m)	Maximum Bankfull Depth (m)
UT-G-SA1 / TOTAL	7/27/08	narrow placid flow channel	1.7	1.2	1.7	0.7
UT 1.490-SA1 / TOTAL	7/29/08	narrow mixed control channel	2.7	0.8	1.3	0.4
UT 1.500-SA1	7/30/08	narrow placid flow channel	0.5	1.3	3.5	0.7
UT 1.500-SA2	7/31/08	narrow shallow contained channel	1.3	1.6	2.7	0.7
UT 1.500-SA3	8/1/08	beaver dam/pond channel	1.3	0.8	2.6	0.6
UT 1.500.10-SA1	8/3/08	narrow mixed control channel	1.0	1.4	3.2	0.4
UT 1.500.20-SA1	7/31/08	shallowly incised muskeg channel	6.5	1.2	2.4	0.5
UT 1.500 TOTAL			1.7	1.3	2.9	0.6

[a] Sample areas were contiguous stream reaches defined by consistent channel types and discharge.

[b] Survey date indicates the first date of survey if Sample Area was surveyed over multiple days.

[c] USFS channel type based on Paustian et al. 1992 classification.

Table B.18-3.
Percent composition of primary habitat types from areas sampled within UT-G and tributaries 1.490 and 1.500 in 2008.

Sample Area (SA)	Length (m)	Average Wetted Width (m)[a]	Total Wetted Area (m^2)[a]	Side Channel (% of Total Wetted Area)	Distributary (% of Total Wetted Area)	Primary Habitat Types (% survey length) / (% wetted area)[b]									
						Backwater/ Slough	Beaver Complex	Cascade	Dry[a]	Obscured[a]	Pond/Lake	Pool	Riffle	Run/Glide	Wetland
UT-G-SA1 / TOTAL	700.9	4.8	3330.6	43	0	0 / 0	9 / 28	0 / 0	0	0	0 / 0	24 / 9	31 / 10	24 / 8	12 / 46
UT 1.490-SA1 / TOTAL	754.6	1.0	726.0	0	0	3 / 14	0 / 0	0 / 0	0	3	0 / 0	3 / 4	21 / 19	64 / 37	5 / 26
UT 1.500-SA1	2275.4	2.3	5326.8	1	0	1 / 2	2 / 31	0 / 0	0	0	0 / 0	1 / 1	45 / 26	50 / 40	0 / 0
UT 1.500-SA2	1456.0	1.6	2332.7	2	0	2 / 9	0 / 0	0 / 0	0	0	0 / 0	2 / 2	57 / 50	40 / 39	0 / 0

UT 1.500.20-SA1	415.0	1.2	516.3	0	0	2 / 12	0 / 0	33 / 22	0	0	0 / 0	1 / 1	64 / 64	1 / 1	0 / 0
UT 1.500 TOTAL	5032.1	3.2	16124.1	1	0	1 / 2	8 / 55	3 / 1	0	0	0 / 0	1 / 1	47 / 20	39 / 21	0 / 0

[a] Dry and obscured habitat units were not included in Average Wetted Width, Total Wetted Area or Percent Wetted Area calculations.

[b] Pond, wetland, dry and obscured habitat types were included in 2008 sampling only.

Table B.18-4.
Descriptive characteristics of primary habitat units from areas sampled within UT-G and tributaries 1.490 and 1.500 in 2008.

Sample Area (SA)	Dominant Substrate	Subdominant Substrate	Eroding Bank (% of Length)	Undercut Bank (% of Length)	Dominant Riparian Vegetation
UT-G-SA1 / TOTAL	organics	sand/silt	0	19	willow shrub
UT 1.490-SA1 / TOTAL	sand/silt	organics	0	15	willow shrub
UT 1.500-SA1	sand/silt	organics	0	1	alder shrub
UT 1.500-SA2	sand/silt	gravel	0	0	alder shrub
UT 1.500-SA3	sand/silt	organics	0	9	other herbaceous
UT 1.500.10-SA1	cobble	sand/silt	0	0	willow shrub/other herbaceous
UT 1.500.20-SA1	gravel	cobble	0	0	alder shrub
UT 1.500 TOTAL	sand/silt	organics	0	2	alder shrub

Table B.18-5.
Summary of 2008 pool habitat data from areas sampled in UT-G and tributaries 1.490 and 1.500.

Sample Area (SA)	Length (km)	Number of Pools			Pool Frequency (# pools/100m)			Pool Area (m^2)			Average Pool Area (m^2)	Average Residual Pool Depth (m)	Number of Holding Pools (≥1m deep; #/100m)
		Primary[a]	Second-ary[b]	Total	Primary	Second-ary	Total	Primary	Second-ary	Total			
UT-G-SA1 / TOTAL	0.7	16	0	16	2.3	0	2.3	305.3	0	305.3	19.1	0.5	2.3
UT 1.490-SA1 / TOTAL	0.75	3	0	3	0.4	0	0.4	28.8	0	28.8	9.6	0.4	0.4
UT 1.500-SA1	2.28	1	0	1	0	0	0	34.6	0	34.6	34.6	0.5	0
UT 1.500-SA2	1.46	6	0	6	0.4	0	0.4	48.5	0	48.5	8.1	0.4	0.4
UT 1.500-SA3	0.8	4	0	4	0.5	0	0.5	22.9	0	22.9	5.7	0.3	0.5
UT 1.500.10-SA1	0.08	0	0	0	0	0	0	0	0	0	0	0	0
UT 1.500.20-SA1	0.42	1	0	1	0.2	0	0.2	4.2	0	4.2	4.2	0.5	0.2
UT 1.500 TOTAL	5.03	12	0	12	0.2	0	0.2	110.1	0	110.1	9.2	0.4	0.2

[a] A primary pool was defined as one that occupied 50% or more of the channel width.
[b] A secondary pool was defined as one that occupied less than 50% of the channel width.

Table B.18-6.
Special habitat features within UT-G and tributaries 1.490 and 1.500, surveyed in 2008. Special features were documented in the field; there are known tributaries that were not documented during the 2008 surveys, including tributaries that were dry, obscured by vegetation, or not connected at the time of the survey.

Sample Area (SA)	Feature Location		Feature Type	Tributary Stream Code	Barrier Characteristics			
	Latitude (WGS84)	Longitude (WGS84)			Type	Status	Height (m)	Length (m)

REACH ANALYSIS

SECTION B.19
KOKTULI RIVER REACH A (KR-A)

Table B.19-1.
List of species found in KR.

Common Name	Scientific Name
Chinook salmon	*Oncorhynchus tshawytscha*
chum salmon	*Oncorhynchus keta*
coho salmon	*Oncorhynchus kisutch*
sockeye salmon	*Oncorhynchus nerka*
arctic grayling	*Thymallus arcticus*
Dolly Varden	*Salvelinus malma*
rainbow trout	*Oncorhynchus mykiss*
whitefish [a]	*Coregoninae*
sculpin [b]	*Cottus* sp.
threespine stickleback	*Gasterosteus aculeatus*
stickleback [c]	*Gasterosteidae*

[a] identified to subfamily, may include round whitefish, humpback whitefish, and least cisco

[b] identified to genus, may include slimy sculpin and coastrange sculpin

[c] identified to family, may include ninespine and threespine stickleback

Table B.19-2.
2004-2008 number of fish observations by lifestage within KR mainstem and associated tributaries from all sampling methods excluding aerial surveys. For all Pacific salmon species, fish that were not recorded as adults were assumed to be juveniles.

Species	Year	Method	Adult				Juvenile				Juvenile/Adult[a]		Total
			Jul	Aug	Sep	Subtotal	Apr	Jul	Aug	Subtotal	Jul	Subtotal	
Chinook salmon	2005	Snorkel	5			5		45		45			50

INSTREAM FLOW: MAIN CHANNEL HABITAT STUDY

1. INTRODUCTION

This report presents the results of the Instream Flow: Main Channel Habitat Study (study), one of several studies that are discussed in Chapter 15, of the Environmental Baseline Document (EBD). Chapter 15 describes baseline environmental conditions associated with fish resources near the Pebble Deposit. The Instream Flow: Main Channel Habitat Study is one component of a suite of interrelated instream flow studies undertaken to characterize existing relationships between stream flow and fish habitat features that include mainstem and off-channel habitat, water temperature, and channel-forming processes. This report (Appendix 15.1C) focuses entirely on habitat-flow relationships in mainstem reaches. The results of the off-channel habitat instream flow study, temperature monitoring/modeling, and fluvial geomorphology studies are provided in Appendix 15.1D, Appendix 15.1E, and Appendix 15.1F, respectively. Unless otherwise stated, the hydrological data discussed in this appendix were obtained during the hydrology studies for Pebble Project, which are described in detail in Chapter 7, for surface hydrology, and Chapter 8, for groundwater hydrology.

The Instream Flow: Main Channel Habitat Study was initiated in 2004, with additional field studies completed in 2005, 2006, 2007, and 2008. The studies completed from 2004 to 2007 were conducted jointly by Ecofish Research Ltd. and HDR; the work in 2008 was completed by R2 Resource Consultants Inc. Work completed in 2004 served to accomplish the following:

- Define the spatial extent of the instream flow studies (consisting of the North Fork Koktuli River (NFK), the South Fork Koktuli River (SFK), Upper Talarik Creek (UT), and a portion of the mainstem Koktuli River (KR).
- Define the general methodological approach best suited for defining habitat-flow relationships.
- Provide the initial establishment of transects that were subsequently sampled in 2005, along with supplemental transects again sampled in 2006 and 2007.

Collectively, the 2004 to 2007 field studies resulted in the establishment of 92 sites, each consisting of single cross-channel transects from which physical and hydraulic data were collected. The 2008 study resulted in the selection and measurement of 46 additional transects that were concentrated in selected areas of each of three river systems (NFK, SFK, and UT) to capture specific habitat features. Since 2008, the focus of the study has been on the analysis of data collected from all five years, hydraulic and habitat model development and calibration, and the derivation of species and lifestage specific habitat-flow relationships for each river system. This report describes the methods used and results from all 5 years of investigation.

This study is closely linked to a number of other studies that have been completed and will collectively contribute to a greater understanding of streamflow and salmonid habitat/population interactions in the

NFK, SFK, UT, and KR systems. The results of these studies are provided as the following series of technical appendices to Chapter 15, of the EBD:

- Appendix 15.1B, Reach Analysis
- Appendix 15.1D, Off-Channel Habitat
- Appendix 15.1E, Open Water River Temperature Model
- Appendix 15.1F, Fluvial Geomorphology Studies

1.1 General Description of Pebble Project

1.1.1 Potentially Affected Watersheds

The study area specific to this report encompasses three watersheds originating near the general Pebble Deposit location: the NFK, SFK, and UT, as well as a portion of the mainstem KR downstream of the NFK and SFK confluence (Figure 9). To place the study area in a regional context, the KR flows for about 39 miles (63 kilometers [km]) before entering the Mulchatna River, which runs 44 miles (70 km) to the Nushagak River. The Nushagak River flows for a distance of about 109 miles (175 km) before discharging into Bristol Bay. The UT drains to Iliamna Lake and from there to Bristol Bay via the Kvichak River, a distance of about 56 miles (90 km). More detailed descriptions of the study watersheds can be found below in Section 2.1.

While a diversity of fish species inhabit the study area, this report focuses primarily on various salmonid species native to the study streams due to their importance to commercial, subsistence, and recreational fisheries, as well as their general ecological importance to the four systems. These species, hereafter referred to as "target species," include the following:

- Four anadromous salmonids—Chinook salmon (*Oncorhynchus tshawytscha*), chum salmon (*O. keta*), coho salmon (*O. kisutch*), and sockeye salmon (*O. nerka*).
- Three non-anadromous salmonids—arctic grayling (*Thymallus arcticus*), Dolly Varden (*Salvelinus malma*), and rainbow trout (*O. mykiss*).

These species inhabit, to varying degrees, all four of the study area streams. Additional information regarding habitat requirements and life histories for each of these species is provided in Section 2.2.

Adult pink salmon (*O. gorbuscha*) were observed in Upper Talarik Creek (EBD Chapter 15) in low numbers during two out of six survey years, 336 salmon in 2006 and 3 salmon in 2007. No fish have been seen subsequently although the number of spawner surveys conducted annually increased and the survey interval decreased for 2007 to 2009. For this study, no established runs of pink salmon were assumed to currently exist in any of the study basins. Therefore, pink salmon was not considered a target fish species for purposes of this study.

1.1.2 Flow Related Effects on Fish Resources

In general, the hydrology of each of the three watersheds in the study area could experience change in one or more of the following ways:

- No change—watershed hydrology is not affected as it relates to fish habitat.
- Temporal changes—the frequency or timing of various flow metrics (e.g., timing of peak flows, timing and duration of base flows, etc.) are altered.
- Spatial changes—hydrologic conditions within the watershed may be altered at specific locations.
- Flow magnitude changes—the overall magnitude of flows may be modified (reduced, increased).
- Rates of flow change—changes in flow may occur more rapidly or more slowly.

Such changes in flow can influence the function of various salmonid lifestages (upstream migration, spawning and egg incubation, fry and juvenile rearing, and juvenile/smolt downstream migration) via alterations in both the quantity and quality of associated habitats.

For example, successful upstream migration of adult salmon depends on sufficient water depths and suitable velocities to allow passage through shallow riffle areas (achieved via swimming) and above cascades and falls (achieved via jumping). Studies have shown that flows that are too low or too high can influence the ability of adult salmonids to migrate upstream to locate suitable spawning areas (Bjornn and Reiser, 1991; Powers and Orsborn, 1985; Stuart, 1964; Thompson, 1972). However, other than beaver dams that are generally located in side channel and off-channel habitats, and temporary ice dams that can occur during ice-out, the mainstem NFK, SFK, and UT systems do not contain any known physical impediments (e.g., falls or cascades) that would preclude or delay upstream movements of adult anadromous salmonids, In contrast, Tributary 1.190 of the UT (hereafter referred to as Tributary UT 1.190) has a series of bedrock cascades and chutes through which successful adult passage could be flow sensitive. A number of other smaller tributaries contain steep cascades and falls that likely limit the extent of anadromous salmonid use in those systems.

The NFK, SFK, and UT systems contain numerous relatively wide riffles and island complexes that could become problematic to upstream passage (via shallow water depths) if flows were severely reduced. Such passage problem conditions occur naturally during certain times of most years in one of the reaches (SFK-C) of the SFK just above Tributary 1.190 (hereafter referred to as Tributary SFK 1.190). From mid-February to late April, flows within this reach typically go subsurface and portions of the stream become dry. This naturally occurring process limits the majority of anadromous salmonid production to downstream reaches. The extent to which low-flow conditions can influence upstream passage in the mainstem NFK and UT and other reaches of the SFK depends on the timing, magnitude, and duration of flow reductions.

Streamflow also plays a direct role in determining the areal extent (i.e., quantity) of habitats that can be used for spawning and rearing. Changes in flow magnitude will change the amount of spawning and rearing habitats in a stream. In general, the amounts of habitat will increase with flow up to a certain point, and then begin to decrease as velocities exceed those used by adults for spawning and juveniles and fry for rearing. Thus, the amounts of available spawning and rearing habitat in the NFK, SFK, and UT systems will vary temporally and spatially in concert with the inter-annual variability in the natural flow regime depending on the timing, magnitude, and duration of flow alterations.

The magnitude of streamflow also has an influence on the quality of the spawning gravels and on maintaining suitable conditions for incubating eggs within the gravels. For the three study streams, this typically occurs as part of the runoff cycle in association with high flows resulting from ice-out and

snowmelt, as well as early fall precipitation events. These flows serve, among other things, to mobilize and transport fine sediments from spawning gravels that are important for increasing gravel permeability and facilitating the interchange of surface and intragravel flows.

The intragravel environment that contains the developing embryos is part of what is termed the hyporheic zone, which can generally be defined as the saturated area beneath the streambed that contains a combination of surface and groundwater flow (Edwards, 1999; Harvey and Wagner,2000), To a large extent, the development and survival of embryos is highly dependent on the environmental conditions existing within this zone (Malcolm et al., 2008), including the concentrations of dissolved oxygen and other water quality constituents, as well as rates of flow. Thus, flows sufficient to maintain the interchange of surface and groundwater flows within the hyporheic zone are important for the successful incubation of deposited eggs, because the flows result in the transport of oxygen to and removal of metabolic wastes from the embryos. The significance of the interchange (i.e. downwelling) of surface with intragravel flows has been demonstrated by Sheridan (1962) and Wells and McNeil (1970). Chapman et al. (1982), Reiser and White (1981), and Wickett (1954) noted relationships between surface flows and intragravel water velocities, suggesting that reductions in the former could reduce the latter.

Areas of groundwater upwelling are also important and are often sought-out for spawning, especially by certain species of anadromous salmonids — including sockeye (Foerster, 1968; Lorenz and Eiler, 1989) and chum salmon (Helle, 1980; Groot and Margolis, 1991). Because groundwater inflow contributes substantially to the streamflows in the three study area streams, any changes to the quantity of groundwater inflow to the streams may alter the quantity of upwelling habitats used for spawning. This could also affect the overall amount of surface flow down gradient from groundwater inflows. Both anadromous and non-anadromous salmonid fry and juveniles rear in freshwater; anadromous salmonids for varying periods of time before out-migrating to the ocean (saltwater). The habitats that constitute rearing areas are diverse and include both main channel and off-channel areas. In the case of the NFK, SFK, UT, and KR systems in the study area, there are extensive mosaics of off-channel habitats that parallel and have physical connections with the mainstem channels. These areas likely provide important fry and juvenile rearing habitats for certain salmonid species.

As in spawning, streamflow is the primary determinant of a number of specific factors that contribute to defining the quality and quantity of suitable rearing habitat. These factors include, but are not limited to: water depth, water velocity, pool volume, water temperature, dissolved oxygen, substrate quality, and in many instances, physical structure and habitat such as large woody debris. Relevant to the first two factors, streamflow has a direct influence on the distribution and quantity of water depths and associated velocities that are most often utilized by fry and juvenile salmonids.

Chapman (1966) considered velocity to be perhaps the most important of the two factors, noting that without suitable velocities, no fish will be present. Studies have shown that fry of salmon and trout typically utilize velocities less than 0.3 feet per second (Chapman and Bjornn, 1969; Everest and Chapman, 1972; Griffith, 1972). As fish grow, they become stronger and are often associated with higher water velocities (Smith and Li, 1983). Shifts in velocity usage by fish have been observed seasonally, presumably in response to water temperature changes. The shifts are generally from higher velocities in the summer feeding periods to lower velocities during the winter holding periods (Chisholm et al., 1987; Tschaplinski and Hartman, 1983).

Water depths used by fry and juveniles can be quite variable, depending on the factors associated with such depths (e.g., substrates, cover, food, velocity, predator density). Newly hatched fry often utilize the extreme edge habitats of a stream where velocities are low and there are few predators. As fish grow, they are capable of using deeper waters with limits of use generally related to some other interrelated parameter—such as water velocity. Bjornn and Reiser (1991) noted that some salmonids are found in higher densities in pools than other habitat types as a result of space availability. This suggests other factors may be acting to regulate such densities; e.g., presence of large woody debris, undercut banks, or overhanging vegetation.

The amount of mainstem flow also dictates the extent to which side channel and off-channel habitats are connected to the mainstem (see Appendix 15.1D). Thus, anything that reduces mainstem flows in the NFK, SFK, and UT systems could not only influence the amount of mainstem rearing habitats, but also the quantity and quality of off-channel habitat areas.

Streamflow can also influence the timing and travel rate at which juvenile/smolt anadromous salmonids move downstream as they progress toward saltwater. In many populations of salmon, the timing of the seaward migration of juvenile/smolts has evolved in concert with the cycle of runoff from adjoining mountains and hills, and has likely done so as a means to increase the survival rates of the fish. As noted earlier, the high flows that occur during this period likely benefit the survival of smolts in both a direct and indirect manner. The high flows allow the smolts to conserve energy since most of the work is done by the stream in the form of kinetic energy. This can have a direct influence on the smolt travel time, ultimate condition when reaching the ocean, and ability to survive the transition to saltwater. The increased turbidities that are generally associated with high flows also afford the smolts protection from predators during downstream passage.

The NFK, SFK, and UT systems generally experience two periods of peak flow: the first related to snowmelt and runoff in the spring, and the second related to periods of increased precipitation during the fall. It is likely, but as yet unverified, that the anadromous salmonid fry/juveniles/smolts within these systems capitalize on these high flow events both in the spring, to facilitate outmigrations to the ocean, and in the fall, to facilitate shorter-distance migrations from the NFK and SFK to the mainstem KR, and from the UT to Iliamna Lake. Thus, if there are any reductions to the peak flows, the effects on survival would depend largely on the magnitude, timing, and duration of flow reductions.

In addition to the direct influence on habitat quantity and quality, and the migratory ability of anadromous salmonids, streamflow provides the necessary energy and forces to create, restore, and maintain the physical characteristics and ecological function of the habitat in and along the channel, This includes the creation of a variety of habitat types (e.g., pools, riffles, runs, etc.) that in combination with local geologies and flora serve to create high quality spawning, nursery, and rearing habitats. High flows are especially important for the following:

- Flushing fine sediments from pools (maintain rearing space) and riffle habitats (maintain food production and spawning areas).
- Moving and recruiting new structure into the channel (e.g., large woody debris and boulders).
- Inundating important riparian and floodplain vegetation that serve to increase bank stability, provide shade, and contribute allochthonous (out of stream) materials/nutrients to the stream.

Streamflow also plays a role in the location, timing, magnitude, and duration of ice formation, and in the process of ice decay, breakup and ice-out. The extent to which any change in streamflow could influence one or more of these processes depends largely on whether and the extent to which flows governing these processes are altered.

1.2 Study Objectives

The brief review above clearly demonstrates the multi-faceted importance of streamflow on the ecology and sustainability of salmonid populations generally. In the context of the Pebble Project, the above review demonstrates the need to understand the relationships and interactions between the existing (baseline) hydrology of the NFK, SFK, UT, and KR and the resulting quantity and quality of salmonid habitat. This understanding, when coupled with species life history, abundance, and distribution information, is useful for characterizing overall baseline conditions.

As noted in Section 1.1, this study is one of several conducted that are focused on understanding the current relationships and dynamics between streamflow and habitat form and function in the three study watersheds. This study centered on defining how streamflow influences the quantity of habitats of different lifestages of target fish species over space and time. The primary objective of the study was to establish relationships between fish habitat and stream surface flow in each of the study streams and selected tributaries. The relationships were developed under current (baseline) conditions and, therefore, reflect how habitats within these streams vary spatially and temporally under current hydrologic regimes.

These relationships can then be used to do the following:

- Characterize existing fish habitats (by target species and lifestage) in each of the systems under baseline conditions.
- Provide environmental data input to the project design process.
- Assess potential changes in physical habitat conditions that could occur from changes in flow regimes.
- Assess temporal and spatial flow change effects on target fish species within the three study area systems, as well as a portion of the mainstem KR downstream of the NFK and SFK confluence.

This report is limited to describing the methods used in developing the habitat-flow relationships and presenting results that describe habitats under baseline flow conditions. Discussion of the results is largely confined to a brief assessment of the trends observed relative to the habitat-flow relationships of the target species for spawning and juvenile rearing lifestages.

2. BACKGROUND INFORMATION

2.1 Description of Study Area and Study Reaches

The study area for the Instream Flow: Mainstem Habitat Study encompasses three watersheds: NFK, SFK, and UT, as well as a portion of the mainstem KR downstream of the confluence of the NFK and SFK (Figure 1). The total distance from the Pebble Deposit to Bristol Bay along the three major river

pathways is 228, 232, and 150 miles (including the 33 miles to transit Iliamna Lake) for the NFK, SFK, and UT drainages, respectively.

In order to present the results of the Pebble Project fish resource studies in an ecologically meaningful framework, a reach-analysis approach has been used to assess spatial trends throughout each of the major watersheds. Specifically, 18 distinct hydrological reaches within the NFK, SFK, and UT watersheds were delineated by R2 Resource Consultants, Inc. (R2), and Buell & Associates, Inc. based on a review of maps and existing data associated with multidisciplinary parameters influencing channel function. Parameters considered included: channel and valley morphology, geology, stream discharge, and surface water temperature. The review resulted in the delineation of six, five, and seven mainstem EBD reaches within the NFK, SFK, and UT, respectively (Figure 1). While no formal reach delineation occurred for the mainstem KR, the portion of the KR in which fish resource studies were conducted during the 2004 through 2008 study period has been treated in the same manner as the other 18 delineated reaches for purposes of results analysis and presentation. See Chapter 15 and Appendix 15.1B for additional details regarding the reach-analysis approach.

The following sections provide brief descriptions of each watershed related to the characteristics and processes influencing the nature and condition of fish habitat, especially as it relates to this study. Additional details are summarized in Chapter 15, Section 15.1. In addition, details on specific watershed physical characteristics in the study area, including climate, geology, physiography, soils, surface water hydrology, groundwater hydrology, and vegetation are provided in Chapters 2, 3, 4, 5, 7, 8, and 13, respectively.

2.1.1 Study Streams

2.1.1.1 North Fork Koktuli River

The NFK is a relatively small drainage within the Nushagak-Mulchatna River system, which is one of eight river basins draining southwest Alaska into Bristol Bay. The NFK basin is situated in the immediate vicinity of the Pebble Deposit, and drains an area that is approximately 113 square miles (292 square km). This drainage area represents 0.9 percent (%) of the Nushagak-Mulchatna River system and 0.3% of the entire Bristol Bay drainage basin. The NFK includes an overall mainstem river length of 36 miles (58 km). The NFK originates on the north slope of Groundhog Mountain, and generally flows west then southwest before joining the SFK to form the Koktuli River. The highest elevation in the NFK drainage is Groundhog Mountain (elevation 3,074 feet; 937 meters); the lowest elevation is at the confluence with the SFK at 580 feet (177 meters; the details and results of the physiography study for Pebble Project are discussed in EBD Chapter 4). The watershed is bounded by a series of low, isolated mountain blocks with Kaskanak Peak to the south, Groundhog and Pig mountains to the east, and Cone Mountain to the north. The northern surface water drainage divide of the NFK is largely undefined.

The mainstem channel network of the NFK has been divided into six stream reaches with similar hydrology, geology, and channel characteristics (Figure 2). The six reach designations, NFK-A through NFK-F, progress from the lowermost to the uppermost sections of the stream network. While other EBD studies related to fish resources have been conducted throughout the NFK, this study focused on establishing transects within the three lowermost reaches.(NFK-A, NFK-B, and NFK-C) that collectively represent the section of stream that contains the majority of mainstem anadromous fish habitat and

supports the highest anadromous salmonid fish use. Additional transects were established in Tributary 1.190 of the NFK (hereafter referred to as Tributary NFK 1.190), which is located at the upstream end of NFK-C (Figure 2). Descriptions of the transect selection process and locations of transects are provided in Section 1.3 of this report. Representative channel characteristics of NFK-A, NFK-B, and NFK-C are depicted in Photos 1, 2, and 3, respectively.

The NFK is primarily a single-thread (i.e. containing a single channel), gravel-bedded river that is relatively straight in high gradient segments and meandering in low gradient segments. Channel slopes range from 0.09% to 0.8%, and average 0.4% (Appendix 15.1F). Tributaries are comprised of both high and moderate gradient, as well as alluvial fan channels. Large woody debris is scarce throughout the NFK due to a general lack of forest vegetation within the riparian zone. Large boulders deposited by retreating glaciers are sporadically located within the NFK channel and provide some instream cover, feeding station, and velocity shelter habitat for fish. Additional instream cover for fish is provided by undercut banks and overhanging vegetation. The primary sources of sediment in the channel are likely from undercut banks and lateral erosion that occurs during high flows and ice break-up processes. The quality of spawning gravels in the NFK is good based on grain size analysis of bulk samples collected from three locations (Appendix 15.1F). The levels of fine sediments in gravels collected from the NFK were lower than levels found in both the SFK and UT. Overall, the concentrations of size fractions that have been related to embryo survival (size fraction less than 0.84 millimeters) and fry emergence (size fraction less than 6.4 millimeters) were well below levels considered harmful (less than 10% and 20%, respectively).

The three lowermost reaches of the NFK (NFK-A, NFK-B, and NFK-C) flow through primarily alluvial valley bottom deposits, consisting predominantly of abandoned stream terraces and deposits composed of re-worked glacial outwash. The stream channels within all three reaches are, overall, considered low gradient. High flows within NFK-A often overflow the channel banks and extend into adjoining floodplains. Associated riparian zones, wetland complexes, and off-channel habitats extend well beyond the stream banks. For most of NFK-B, the channel flows through a relatively narrow (approximately 1,525-foot; 465 meter wide) valley bottom bordered by low hills. NFK-C flows across glacial outwash and moraine deposits.

Based on mesohabitat mapping reported in Appendix 15.1B, riffles are the predominant habitat type in NFK-A, NFK-B, and NFK-C, with runs a subdominant habitat feature (Figure 3). Pool habitats are relatively sparse in all mainstem NFK reaches. NFK 1.190 is also dominated by riffle habitat and, to a lesser extent, runs –with small amounts of pool, cascade, and backwater slough habitat. The mesohabitat data in the mainstem reaches were further analyzed to identify and assign habitat types associated with island complexes, since these represented a prominent feature of the system. The resulting habitat composition shows that riffles, runs, and island complexes are the primary habitat types in NFK-A, NFK-B, and NFK-C (Figure 3).

Seasonal flows in the NFK generally have two peaks, similar to other streams in Southwestern Alaska, and similar to the adjoining watersheds in the study area. The first peak occurs during the spring snowmelt season (early to late May), while the second peak occurs during the fall rainy season (late August to early October). These peaks are separated by two low flow seasons: a summer low flow (during the first half of August), and a winter low flow (late March to late April). The average annual flow in the NFK was 270 cubic feet per second (cfs) during calendar years 2005 through 2008 at Hydrology Gage NK100A (U.S. Geological Survey [USGS] Gage No. 15302250). This discharge is equivalent to an

average annual unit runoff of 31 inches (78 centimeters) from the 106-square-mile (274-square-km) basin area at the gage.

Runoff is flashy in steep tributaries draining the isolated mountain blocks where groundwater storage is limited. In contrast, the mainstem NFK shows a pronounced groundwater influence. Upstream from the upper two-thirds of NFK-C, the river is a "losing" stream. In this area, the NFK flows across unconsolidated outwash fan sediments with a high infiltration capacity, and water generated by stream flow, precipitation, and snowmelt rapidly infiltrates into a shallow aquifer (Chapter 7). The groundwater flows down valley, emerging at the downstream end of the glacial outwash deposits. The downstream third of NFK-C and a short stretch of NFK-B are "gaining" reaches that exhibit evidence of substantial groundwater upwelling (Chapter 7 and Chapter 8). Similarly, the downstream portion of NFK-A (downstream from Hydrology Gage NK100A) receives groundwater inflow, increasing the local surface water discharges at these locations. Hydrologic investigations also suggest there may be a small amount of cross-basin transfer of groundwater from the NFK to UT across the low drainage divides southeast of Groundhog Mountain upstream of Gaging Station UT100E (Chapter 7). The hydrologic regime of the NFK has a major influence on the functionality and usability of fish habitat and, in turn, the distribution and abundance of fish that utilize the watershed.

2.1.1.2 South Fork Koktuli River

The SFK (Figure 4) is another relatively small drainage of the Nushagak-Mulchatna River system. Like the NFK, the headwaters of the SFK are situated in the immediate vicinity of the Pebble Deposit area. The SFK drainage area comprises 107 square miles (277 square km), which represents about 0.8% of the Nushagak-Mulchatna River system and 0.3% of the entire Bristol Bay drainage basin. The SFK includes an overall mainstem stream length of approximately 40 miles (64 km). The SFK originates on the east flank of Kaskanak Mountain, northwest of Frying Pan Lake. The SFK flows south then west before joining the NFK to form the Koktuli River. The highest elevation in the SFK drainage is Kaskanak Mountain (elevation 2,760 feet or 841 meters). The lowest elevation in the basin is at the confluence with the NFK at 580 feet (177 meters; details and results of the physiography for the study area are discussed in EBD Chapter 4). The watershed is bounded by a series of low, isolated mountain blocks with Kaskanak Peak to the west, Koktuli Peak to the east, and Sharp Mountain to the south. Like the NFK, the northern surface water drainage divide is not well defined.

The mainstem channel network of the SFK has been divided into five stream reaches with similar hydrology, geology, and channel characteristics (Figure 4). The five reach designations (SFK-A through SFK-E) progress from the lowermost to the uppermost section of the stream network; SFK-E includes an impounded segment near the headwaters formed by Frying Pan Lake. Like the NFK, this study focused on the three lowermost reaches of the SFK (containing the greatest amount of useable anadromous fish habitat) by establishing instream flow transects in SFK-A, SFK-B, and SFK-C. Additional transects were established in SFK 1.190, a major tributary joining the SFK at the upstream end of SFK-B. Representative channel characteristics of SFK-A, SFK-B, and SFK-C are depicted in Photos 4, 5, and 6, respectively.

A large and variable portion of SFK-C has at times exhibited intermittent flow conditions during summer and winter months. However, the severity and duration of these events has varied by year. For example, based on flow records from Gaging Station SK100C during 2007, there was no surface flow in SFK-C for a period of 40 days between early July and early September 2007. Conversely, the reach did not

completely dry-up in 2006. When these channels dewater, fish must either move upstream or downstream to areas of ponded or flowing water, or become stranded within the influenced reach.

The SFK is primarily a single-thread, gravel-bedded channel with a geomorphic tendency toward a meandering pattern. Channel slopes in the SFK are the lowest of the three basins, ranging from 0.03 to 0.6% and averaging 0.2% (Appendix 15.1F). Large woody debris is scarce throughout the SFK because of a general lack of forest vegetation within the riparian zone. Large boulders deposited by retreating glaciers are sporadically located in the channel and provide instream cover, feeding station, and velocity shelter habitat for fish. Additional instream cover for fish is provided by undercut banks and overhanging vegetation.

Like the NFK, the primary sources of sediment in the channel are from undercut banks and lateral erosion that occurs during high flows and ice break-up processes. The quality of spawning gravels is good, based on grain size analysis of bulk samples collected from three locations in the SFK (Appendix 15.1F). Although the levels of fine sediments in gravels collected from the SFK were higher than levels found in samples from the NFK and UT, the concentrations of size fractions that have been related to embryo survival (size fraction less than 0.84 millimeters) and fry emergence (less than 6.4 millimeters) were all below levels considered harmful (less than 12% and 20%, respectively, after Chapman and McLeod, 1987; Kondolf, 2000; Lotspeich and Everest, 1981 Shirazi et al., 1981).

Valley bottom deposits in the two lowermost reaches (SFK-A and SFK-B, i.e., downstream of SFK1.190) consist of reworked glacial outwash material, including abandoned stream terraces and recent alluvial deposits. These reaches are flanked by glacial moraine and drift deposits. High flows typically overflow the banks, and large channels are bordered by floodplains and former stream terraces. Associated riparian zones, wetland complexes, and off-channel habitat can extend well beyond the stream banks. Sediment sources consist primarily of fluvial transport from upstream reaches and bank erosion. SFK-A and SFK-B generally possess an alluvial channel morphology that appears to reflect adjustment to the post-glacial flow regime (Appendix 15.1F). SFK-C, located upstream of Tributary SFK 1.190, flows through glacial lacustrine (related to a lake environment) deposits. SFK-C is relatively low gradient compared to the rest of the mainstem, with channel slopes on the order of 0.03% to 0.07%.

Results of mesohabitat data mapping indicate that riffle and run/glide habitats are the predominant habitat types in SFK-A, SFK-B, and SFK-C, whereas pools are relatively sparse (Appendix 15.1B). SFK 1.190 is dominated by riffle habitat with lesser amounts of run, pool, and backwater slough habitat. As for the NFK, the aforementioned mesohabitat data were further analyzed to identify and assign habitat types associated with island complexes. The resulting habitat composition shows that riffles, runs, and island complexes are the primary habitat types in SFK-A and SFK-B (Figure 5). However, island complexes were less common in SFK-C, where run and riffle habitat dominated.

Seasonal flows in the SFK generally have two peaks, the first occurring during the spring snowmelt season (early to late May), the second during the fall rainy season (late August to early October). These peaks are separated by two low flow seasons: a summer low flow (during the first half of August), and a winter low flow (late March to early May). The average annual flow in the SFK was 191 cfs during calendar years 2005 through 2008 at Hydrology Gage SK100B (USGS Gage No. 15302200). This discharge is equivalent to an average annual unit runoff of 33 inches (84 cm) from the 69–square-mile (180-square-km) basin area at the gage. The lowermost gage in the SFK watershed (SK 100A), located

prior to the confluence with the NFK, recorded a mean annual discharge of 269 cfs between 2005 and 2008.

The mainstem SFK exhibits a pronounced groundwater influence. From the outlet of Frying Pan Lake downstream through the upstream third of SFK-B, the river flows generally decrease in a downstream direction as water infiltrates into permeable glacial outwash sediments. As noted above, portions of this section of the SFK have gone dry in the late summer and early fall, and have also exhibited subsurface flows during the winter baseflow period. For example, in March 2005, flows were 7.7 cfs at the SK100F gage (River Kilometer [RK] 54.7) and 0 cfs at the SK100C gage (RK 35.8), despite the contributing drainage area more than tripling between the two gage sites from 11.9 square miles (31 square km) to over 37.5 square miles (96 square km). In addition, approximately 25 cfs of groundwater, flows out of the SFK basin and emerges in Tributary UT 1.190.

Stream flow in SFK is augmented by groundwater in the lower portions of SFK-B and SFK-A, where the river flows across the western end of the terminal moraine and enters the relatively narrow valley between Kaskanak Mountain and Sharp Mountain. Springs, seeps, and upwelling groundwater are common in the upstream end of this reach, and baseflows can increase from 0.3 to almost 27 cfs over a distance of 2.5 miles (4 km), with less than a 10% increase in contributing surface area (Chapter 7). Groundwater contributions influence conditions in this portion of the river year round. Ice-free (open water) conditions reflect the warming influence of groundwater observed throughout the winter. Like the NFK, the hydrologic regime of the SFK has a substantial influence on the functionality and usability of fish habitat, and in turn, the distribution and abundance of fish that utilize the watershed.

2.1.1.3 Upper Talarik Creek

The UT watershed (Figure 6) drains an area of about 135 square miles (350 square km) and is part of the Kvichak River system, one of eight river basins draining SW Alaska into Bristol Bay. From its headwaters, which are located in the immediate vicinity of the Pebble Deposit area, the stream flows in a south-southwesterly direction for about 39 miles (62 km) to where it enters Iliamna Lake. The UT represents about 1.7% of the Kvichak River system and 0.3% of the entire Bristol Bay drainage basin. The highest elevation in the UT drainage is Pig Mountain (elevation 2,809 feet; 856 meters), while the lowest elevation is at the stream outlet to Iliamna Lake (elevation about 46 feet; 14 meters). The watershed is bounded by a series of low, isolated mountain blocks: Koktuli Peak to the west, the Pig Mountains to the northwest, Dalton Mountain to the northeast, and a long unnamed ridge that separates the UT drainage from the Newhalen River to the east. The northwestern surface water drainage divide between the NFK and UT is inconspicuous.

The mainstem channel network of the UT basin has been divided into seven stream reaches with similar broad-scale hydrologic, geologic, and channel characteristics (Figure 6). These reach designations (UT-A through UT-G) progress from the lowermost to uppermost section of the stream network. This study focused on all reaches of the UT, except the lowermost (UT-A) and uppermost (UT-G), by establishing instream flow transects in UT-B through UT-F. The uppermost reach is located above the majority of spawning habitat and is also proximal to the Pebble Deposit. The lowermost reach is below First Creek which contributes substantial flow to UT. Additional transects were established in Tributary UT 1.190, which joins the UT at the upstream end of UT-C. Representative channel characteristics of UT-B through UT-F are depicted in Photos 7 through 11, respectively.

The UT is primarily a single-thread, gravel-bedded channel that is relatively straight along much of its length, except where the river valley and floodplain widens and multiple channels have formed. The channel slopes of the UT are generally steeper than those of the NFK and SFK, ranging from 0.1 to 2.0% and averaging 0.5% (Appendix 15.1F). As in the NFK and SFK, large woody debris is scarce in the upper portion of the basin due to a general lack of forest vegetation in the riparian zone. The lower reaches, however, are associated with larger trees and large woody debris is more prevalent.

Alluvial transport and deposition are prevalent within most of UT-B and the entire length of UT-A. Within these areas, high flows typically overflow the banks, and channels are bordered by relatively wide floodplains. Associated riparian zones (some supporting large trees), wetland complexes, and off-channel habitat extend well beyond the stream banks. Large woody debris is present within these sections of the river and serves to create and maintain habitat diversity. In the upper third of UT-B and in UT-C, the river channel is low gradient, contained, and flows through a relatively narrow (1,300- to 2,600-foot; 400- to 800-meter) valley bottom, bordered by low hills to the west and carved glacial deposits to the east. UT-D, UT-E, and the lower half of UT-F are classified as alluvial floodplain channels that have formed by re-working glacial outwash deposits. Multiple former stream terraces and colluvial slopes occur where the present stream channel has downcut through glacial outwash and lacustrine deposits. Large woody debris is relatively sparse within these reaches due to a lack of source trees from the riparian zone. In the upper half of UT-F and UT-G, the channel flows across deep glacial lacustrine deposits.

Based on mesohabitat mapping reported in Appendix 15.1B, riffles are the predominant and run/glide the subdominant habitat features in UT-A, UT-B, and UT-G. Conversely, run/glide is dominant, and riffles subdominant in UT-C through UT-F. Pool habitats represented a substantial proportion of the habitat composition only within UT-E and UT-F. The frequency of pool habitats remained low in all other UT reaches. UT 1.190 is also dominated by riffle habitat, with only a small amount of cascade habitat. The mesohabitat data were analyzed to identify and assign habitat types associated with island complexes. The resulting habitat composition shows that riffles, runs, and island complexes are the primary habitat types in UT-B through UT-E, although pools were also substantial in UT-D and UT-E (Figure 7). Island complexes were less common in UT-F.

Like the NFK and SFK watersheds, stream flows in the UT are driven by runoff from spring snowmelt and summer/fall rains. Available data suggest surface water flows generally decline from October through April, are highest in late April to late May as a result of snowmelt, then reach a secondary peak in the late summer/early fall (late August to early) as a result of rainfall. Flows are lowest in the early spring (March to April) and during mid-summer (July and early August). Base flows tend to remain high in both winter and late summer due to groundwater storage. The average annual flow in UT was 232 cfs during calendar years 2005 through 2008 at Hydrology Gage UT100B (USGS Gage No. 15300250). This discharge is equivalent to an average annual unit runoff of 32 inches (82 centimeters) from the 86.2-square-mile (223-square-km) basin area at the gage. The lowermost gage in the UT watershed (UT 100A_PC3) recorded a mean annual discharge of 382 cfs during 2008.

Streamflows in the UT are also influenced by groundwater inflow. Approximately 25 cfs of flow enters the UT basin through the cross-basin transfer of groundwater from the SFK. The groundwater flows eastward from the SFK, likely along flow paths formed by former glacial meltwater channels, and emerges in Tributary UT 1.190. Tributary UT 1.190 exhibits a much higher unit runoff (i.e., flow per unit watershed area) and a much more stable hydrograph than other streams in the UT watershed, reflecting

the groundwater influence. Flow records indicate the downstream portion of UT-F (downstream from Hydrology Gage UT100D) and UT-D also receive groundwater inflow, portions of which remain ice-free during winter months.

2.1.1.4 Mainstem Koktuli River

The KR encompasses a moderate-sized drainage (Figure 8) of the Nushagak-Mulchatna River system that drains a 218-square-mile (565-square-km; 140,000-acre) area, or 1.7% of the Nushagak-Mulchatna River system and 0.6% of the entire Bristol Bay drainage basin. The KR has an overall mainstem river length of approximately 39 miles (63 km). The KR originates at the confluence of the North Fork and South Fork Koktuli rivers and flows northwesterly for about 29 miles (46 km) until it exits the study area at the confluence with the Swan River. The highest elevation in the KR drainage is Cone Mountain (elevation 2,760 feet; 841 meters); the lowest elevation in the basin is at the confluence with the Swan River at 580 feet (177 meters). The watershed is bounded by a series of low, isolated mountain blocks with Cone Mountain to the northeast.

The upper reach of the mainstem KR is more than 31 miles (50 km) downstream from the Pebble Deposit, and the study efforts in the KR were less intense than in the other three watersheds. Consequently, less is known regarding fish habitat and channel characteristics in this part of the study area. Habitat composition in this basin was determined during the transect selection process that occurred in the uppermost section of the river. Habitats within the section were composed mostly of riffle and run habitat, with lesser amounts of island complexes (Figure 8). Field crews also noted some pools present in this reach of the Koktuli River, although the pools were not associated with designated transects.

2.1.2 Fish of the Study Streams

The fish resources within the study area include five species of anadromous Pacific salmon, at least four species of non-anadromous salmonids, as well as numerous non-salmonid fishes. The term anadromous refers to the group of fish that spend the majority of their life cycle in the ocean where they grow and mature, but the reproductive and initial juvenile rearing stages of their life cycle are spent in freshwater. The freshwater existence commences with the adults entering rivers and streams and migrating upstream until they find their natal stream (i.e., the stream of their origin), where, when conditions are right, the fish spawn. Pacific salmon are semelparous, meaning that all adults die after spawning. Depending on the species of Pacific salmon, the resulting progeny may spend from a relatively short time (months) upwards to several years rearing in freshwater before migrating back downstream to the ocean. It is during this period of outmigration that the juvenile salmon are exposed to and imprint on the bouquet of odors inherent to the waters they encounter that enables them, as adults via olfactory cues, to retrace the path back to their stream of origin. For purposes of this document, non-anadromous fish are those that spend their entire life cycle in freshwater. Detailed information regarding each species is provided in Appendix 15.1A and Appendix 15.1B. Summary information of each species is provided in the specific watershed descriptions below.

The runs of Pacific salmon inhabiting the study area fall within the Bristol Bay management area. This area provides the largest commercial sockeye salmon fishery in the world, as well as important fisheries for Chinook, chum, coho, and pink salmon (Jones et al., 2009). The Bristol Bay management area includes nine major river systems and is divided into five management districts. As a tributary to the

Mulchatna and Nushagak rivers, the Koktuli River is a component of the Nushagak District. Upper Talarik Creek, as a tributary to Iliamna Lake and the Kvichak River, is a component of the Naknek-Kvichak District.

Non-salmon fishes also represent important components of subsistence and recreational fisheries in the Bristol Bay area. For example, species present in the study area that are used for subsistence purposes in the Kvichak River and Iliamna Lake area include arctic grayling, Dolly Varden, rainbow trout, whitefish species, burbot, and northern pike (Krieg et al., 2005). Several of these species are also targeted for sport harvest in the Bristol Bay sport fish management area, including arctic grayling, Dolly Varden, rainbow trout, and northern pike (Dye et al., 2006).

The general life history of Pacific salmon species involves adults constructing nests (redds) in gravel beds in which spawning occurs, emergence of fry from the gravels, a period of freshwater rearing of fry and juveniles, followed by the downstream migration of juveniles/smolts (smolts are juvenile fish that have undergone physiological changes preparatory to transitioning to saltwater) to the ocean for feeding and maturation, and subsequent return of adults to natal sites for spawning and completion of their life cycle. There are many variations on the timing and duration of these lifecycles (termed periodicity) both among species, and from year-to-year for the same species. However, all salmonids share a need for the following habitat conditions: sufficient food supply; cool, high quality flowing water; high dissolved oxygen concentrations; and unimpeded migratory access to and from spawning and rearing areas (Spence et al., 1996).

The general periodicities of the different life history stages of the target species are shown in Table 1. The specific times noted were in part based on a general understanding of the local populations as described in the published literature, as well as site specific data collected as part of fish studies. The periodicities are subject to revision pending acquisition of new data and information and may not correspond exactly with the largely literature derived life history descriptions presented below. The distribution of the target species in the study area by reach is presented in Table 2. Species information specific to individual basins in the study area can be found in Chapter 15, Section 15.1.

2.1.2.1 Chinook Salmon

Chinook salmon is the largest species of Pacific salmon, typically weighing around 20 pounds (9 kilograms [kg]) at maturity, although some may exceed 100 pounds (45 kg). Their range extends from northern Hokkaido, Japan, to the Anadyr River in Siberia and from the San Joaquin River in Central California to the Coppermine River in the Canadian Arctic (Healey, 1991). In Alaska, Chinook salmon occur in large coastal rivers from the southern tip of Alaska's panhandle northward to Point Hope (Mecklenburg et al., 2002). Chinook salmon have been documented in several Bristol Bay tributaries, including the Kvichak and Nushagak River basins (Johnson and Weiss, 2007) and are present in the NFK, SFK, UT, and KR within the study area (Chapter 15).

Chinook salmon mature and begin their spawning migration between 3 and 6 years of age, but most spawning adults are ages 4 or 5 (Healey, 1991). In northwestern Canada and Alaska, adult Chinook salmon migrate to freshwater spawning grounds between late May and July, although this period may extend from April to September in some locations (Healey, 1991). While spawning generally takes place from July to November, timing varies regionally and depends on the distance and duration of upriver migration (Morrow, 1980; Scott and Crossman, 1973). Northern populations, such as those in Alaska,

tend to spawn from July through September (Healey, 1991). Based on aerial surveys in the NFK, SFK, and UT from 2004 to 2008, peak adult counts in the study area typically occur in late July or early August (Chapter 15).

Chinook salmon require deep holding water and sufficient discharge to successfully complete their upstream migration. They typically spawn in mainstem reaches where hydraulic and substrate requirements are met, often at the head of a riffle upstream of its crest. As the largest of the Pacific salmon species, Chinook salmon tend to spawn in higher water velocities (1 to 3 feet per second) and in larger substrates (up to 6 inches) than other salmon (Burner, 1951; Raleigh et al., 1986). Spawning depths vary widely, from 2 to 180 inches (5 to 457 centimeters), with average spawning depths of at least 12 inches (30 centimeters; Healey, 1991). Adults die following reproduction and egg deposition into one or more redds.

Chinook salmon egg incubation varies with temperature, resulting in an increased time to hatching at lower temperatures. Successful incubation requires clean water percolating through spawning gravels at temperatures less than 16 degrees Celsius (°C; Healey, 1991). Chinook salmon eggs require 882 to 991 temperature units on average before hatching (1 temperature unit = 1 °C above freezing for 24 hours; Beauchamp et al., 1983). After hatching, the young remain in the gravel for 2 to 3 weeks before emerging as free-swimming, feeding fry (Morrow, 1980; Wydoski and Whitney, 2003). While some juvenile Chinook salmon may rapidly disperse to sea, this life history pattern tends to be absent in locations over 56 degrees north latitude, such as Alaska (Quinn, 2005). In these northern locations, most juvenile Chinook salmon remain in freshwater streams for 1 year before beginning their outmigration to sea, and some will remain in freshwater for 2 years (Morrow, 1980; Quinn, 2005).

Juvenile Chinook salmon occupy a variety of habitats in freshwater. Younger, smaller fry inhabit stream margins, eddies, backwaters, and side channels and are often associated with fallen trees, root wads, and areas with bank cover. As they increase in size, juvenile Chinook salmon move into stream and river habitats with increasing velocities. This movement is associated with a shift from predominantly sandy substrates to those with larger-sized gravel and boulders (Healey, 1991).

2.1.2.2 Coho Salmon

Coho salmon is moderate sized relative to other Pacific salmon, typically weighing 8 to 10 pounds (4 to 5 kg). This species is widely distributed throughout the North Pacific basin, from the Sea of Japan north to Point Hope, Alaska, and south to the Sacramento River in California (Sandercock, 1991). Along the Pacific coast of Alaska, coho salmon inhabit coastal rivers and streams including the Kvichak and Nushagak River basins. Coho salmon are present in the NFK, SFK, UT, and KR within the study area (Chapter 15).

Coho salmon typically return to their natal streams to spawn at age 3 after spending 18 to 24 months (up to 3 years) in the marine environment. However, precocious males that reach maturity during their first (referred to as “jacks”) or second year are a natural component of many Alaska coho salmon populations (Sandercock, 1991). North American coho salmon typically spawn from October to March, although entry into freshwater and, consequently, spawning time varies in different populations and environmental conditions (Morrow, 1980; Sandercock, 1991). In northwestern Canada and Alaska, adult coho salmon may begin their upstream migrations as early as late June or July with most spawning occurring in November. In the Bristol Bay area, runs peak in August and September (McPhail and Lindsey, 1970).

Based on aerial surveys from 2004 to 2008 in the NFK, SFK, and UT, peak adult counts in the study area typically occur during the month of September (Chapter 15).

Adult coho salmon require deep holding cover for resting during upstream migration, and sufficient discharge for upstream movement into tributaries. The minimum upstream passage depth criteria for adult coho salmon is 7 to 8 inches (18 to 20 centimeters; Thompson, 1974; Laufle et al., 1986). For spawning and incubation, coho salmon require clean gravel and cool water temperatures (11°C to 15°C preferred; Reiser and Bjornn, 1979). The length of incubation for coho salmon ranges from 35 to 101 days (Laufle et al., 1986). In Alaska, the incubation period for coho salmon ranges from 42 to 56 days (McPhail and Lindsey, 1970). After hatching, larval fish typically spend several weeks in the gravel before emerging (Laufle et al., 1986; McMahon, 1983). Newly emerged fry usually congregate along stream margins and in backwater pools.

During their first winter, juveniles use a variety of slower water habitats including alcoves, beaver ponds (also referred to as beaver complexes), and side channels (Nickelson et al., 1992). In the winter, these habitats provide deep water rearing and holding areas that are less vulnerable to freezing, as well as low-velocity refuge areas that are protected from high flows and impacts resulting from ice out. Complex, large woody structures and side channels are also important habitats for coho salmon during summer low-flow periods, inasmuch as they tend to create and provide pool habitats (Grette and Salo, 1986). As juveniles grow, they typically disperse into more riffle-type habitats and aggressively defend their territory, which results in displacement of excess juveniles downstream to potentially less favorable areas (Sandercock, 1991). Once territories are established, individuals typically rear in selected areas of the stream, feeding on drifting benthic organisms and terrestrial insects until the following spring (Hart, 1973). Juvenile coho salmon rearing time in freshwater is typically about 15 months, although some juveniles will remain in freshwater for up to 2 years (Sandercock, 1991). Smolt outmigration begins in February and may continue into June; however, in more northern populations, outmigration is likely to occur later and extend into July or August.

2.1.2.3 Chum Salmon

Among Pacific salmon, the chum salmon is second only to Chinook salmon in size. Adult chum salmon can weigh up to 45 pounds (20 kg), but are typically around 10 to 15 pounds (5 to 7 kg). This species has the widest distribution among Pacific salmon, ranging from Korea to the Lena River in Russia and from the Mackenzie River in the Canadian Arctic down to Monterey, California (Salo, 1991). On the Pacific coast of North America, major chum salmon runs occur from the Kotzebue Sound of northwestern Alaska southward to Tillamook Bay, Oregon. Major runs in Bristol Bay tributaries include the Togiak, Nushagak, and Kvichak River basins (Salo, 1991). This species is also present in the NFK, SFK, UT, and KR within the study area (Chapter 15).

Chum salmon mature between 2 and 6 years of age (Salo, 1991). Chum salmon spend comparatively little time in freshwater and generally spawn soon after migrating into the lower reaches of streams (Quinn, 2005). While chum salmon do not typically migrate long distances in freshwater reaches, spawning occurs up to 1,736 miles (2,800 km) from the sea in the Yukon River, Alaska (Salo, 1991). Upstream migration can be rapid, with rates of 30 miles per day recorded (Groot and Margolis, 1991). In Alaska and northwestern Canada, adults tend to begin their spawning migration in early June (McPhail and Lindsey, 1970). Major chum salmon runs in the tributaries of Bristol Bay tend to peak in early July and subside by

the end of the month (Salo, 1991). Based on aerial surveys from 2004 to 2008 in the NFK, SFK, and UT, peak adult counts of chum salmon in the study area typically occur from mid to late July (Chapter 15).

Preferred spawning areas of chum salmon include groundwater-fed streams or at the heads of riffles (Grette and Salo, 1986). Upwelling is important in the selection of redd sites and spawning often takes place in shallow, slower velocity streams and side channels (Johnson et al., 1997). However, chum salmon will also utilize spawning areas within mainstem rivers and side channels. Chum salmon die within a few days after spawning, with females often attending to their redds during this period (Morrow, 1980).

Incubation times are largely based on water temperature. For example, eggs incubating at 15ºC hatch approximately 100 days earlier than eggs incubating at 4ºC. The general fitness and quality of emergent fry depends, in part, on the: concentration of dissolved oxygen in the water, gravel composition, spawner density, stream discharge, and genetic characteristics (Salo, 1991). Since chum salmon embryos typically hatch during periods of ice-cover, the actual timing of hatching in Alaska is largely unknown, but it is expected to be later than in southern populations. In British Columbia, hatching occurs between December and February (McPhail and Lindsey, 1970; Morrow, 1980). Juvenile chum salmon remain in the gravel for several weeks after hatching. Following emergence from the gravel, juveniles then rear in freshwater for a period of a few days to several weeks before migrating downstream toward estuarine waters (Grette and Salo, 1986). During this period of migration, the juveniles actively feed on aquatic invertebrates (Salo, 1991). Generally, chum salmon outmigration occurs between mid-spring and late summer, but tends to occur later in the season in more northern latitudes and takes longer in larger river systems (Salo, 1991).

Juvenile chum salmon spend more time rearing in estuaries than other anadromous salmon, often remaining for several months before dispersing into saltwater in late July or August (Johnson et al., 1997; Scott and Crossman, 1973). Juveniles may remain near the mouths of their natal rivers after entering the estuary or may disperse rapidly throughout the estuarine system into tidal creeks and sloughs. Because of their increased rearing time in estuaries, estuarine habitat is thought to play a major role in determining subsequent adult returns to freshwater (Johnson et al., 1997). A variety of microhabitats and food sources within the estuary may be used by chum salmon. Microhabitat selection may vary with fish size and environmental conditions, such as food, availability refuge habitats, predator presence, and salinity (Quinn, 2005).

2.1.2.4 Sockeye Salmon

Sockeye salmon are generally smaller than the aforementioned species of Pacific salmon, averaging 5 to 8 pounds (2 to 4 kg), but reaching up to 15 pounds (7kg). Sockeye salmon populations occur in Asia from the Kuril Islands north to the Gulf of Anadyr and in North America from the Sacramento River, California, to Point Hope, Alaska (Burgner, 1991). In North America, sockeye salmon are primarily distributed from the Columbia River north to the Kuskokwim River in Alaska (Quinn, 2005). Among populations in Alaska and northwestern Canada, one of the largest spawning sockeye salmon complexes occurs in Alaska's Bristol Bay basin (McPhail and Lindsey, 1970). Within the study area, sockeye salmon are present in the NFK, SFK, UT, and KR (Chapter 15).

Sockeye salmon are unique among *Oncorhynchus* species in that the rearing of juveniles largely takes place in lakes. The Bristol Bay basin contains a large number of lakes and, consequently, large spawning

complexes of sockeye salmon. Life history characteristics of these populations have been well studied (Burgner, 1991). In the Bristol Bay basin, adult sockeye salmon runs occur from early June to August, with 80% of the run occurring within a 12- to 14-day period (Burgner, 1991). Spawning typically takes place in August and September (McPhail and Lindsey, 1970). Within the study area, peak adult counts typically occur from late July to early August, based on aerial surveys from 2004 to 2008 in the NFK, SFK, and UT (Chapter 15).

Because juvenile sockeye salmon typically rear in freshwater lakes, adults tend to spawn in systems associated with lakes. Habitats used for sockeye salmon spawning are diverse and include lake tributaries, outlet rivers, lake beaches, and spring-fed ponds and side channels (Burgner, 1991; Quinn, 2005). Redds may be constructed in a variety of substrates, ranging from fine gravels in side channels to coarse lake shore gravels and rocky beaches (Burgner, 1991).

Egg incubation takes between 6 and 9 weeks and, as is the case with other salmonid species, incubation time depends on temperature (McPhail and Lindsey, 1970). After spending 2 to 3 weeks in the gravel, sockeye salmon fry move, either upstream or downstream, from the area around the redd into a lake associated with the spawning stream. Sockeye salmon juveniles spend 1 to 2 years in a lake, growing and beginning to smolt (McPhail and Lindsey, 1970; Quinn, 2005). The seaward outmigration of sockeye salmon smolts begins after ice break-up, and in the Bristol Bay basin, peak outmigrations occur in June when water temperatures are around 4°C (McPhail and Lindsey, 1970; Morrow, 1980). Adults return to their natal stream to spawn after spending 1 to 4 years in the ocean (Mecklenburg et al., 2002).

2.1.2.5 Arctic Grayling

Arctic grayling occur in mainland Asia and North America. In Asia, they are distributed east of the Ob and Kara rivers in Siberia and north of the Eroo River in northern Mongolia. The North American distribution of arctic grayling includes Alaska and northern Canada eastward to the Hudson Bay; and this species has also been documented in the Missouri River headwaters of Montana (Mecklenburg et al., 2002). Arctic grayling occur naturally throughout most of Alaska and are also found in the St. Lawrence and Nunivak islands (Mecklenburg et al., 2002; Morrow, 1980). Within the study area, arctic grayling are present in the NFK, SFK, UT, and KR systems (Chapter 15).

Arctic grayling occupy freshwater habitats, preferring clear, cold water in lakes, large rivers, and rocky streams (Mecklenburg et al., 2002). While inhabiting lakes, they tend to remain near rocky shores and stream mouths. While swimming in streams, arctic grayling can often be found midstream at a short distance below the surface (McPhail and Lindsey, 1970). Some arctic grayling use upstream pools as summer feeding habitat, and most overwinter in the deep waters of lakes and mainstem channels. Juveniles are thought to occupy similar seasonal habitats as adults, but the territorial behaviors of larger fish and prey item availability are likely to limit juvenile fish distribution and create habitat partitioning (Morrow, 1980).

Prior to spawning, arctic grayling migrate upstream from overwintering sites in the deep waters of lakes or mainstem channels to spawning sites located in smaller tributaries (Morrow, 1980; Scott and Crossman, 1973). Prior to their spawning migration, arctic grayling typically stage at tributary mouths and may begin their migration via channels cut in the ice by surface runoff. Little is known about arctic grayling migration distances, but movements of up to 99 miles (160 km) have been documented (Morrow, 1980). In Alaska and northwestern Canada, spawning reportedly takes place from May through June

(McPhail and Lindsey, 1970; Morrow 1980). While no formal redd is constructed by the female, tail-quivering behavior associated with reproduction creates a shallow depression in the substrate. Eggs and milt are released over this depression (Morrow, 1980). After spawning, adults may return to lakes or rivers, or they may migrate further upstream to occupy stream pools for a summer feeding season (Morrow, 1980; Scott and Crossman, 1973). For those that migrate further upstream, a downstream return migration to overwintering sites takes place in mid-September (Morrow, 1980). Arctic grayling spawn multiple times over their lifespan and may live up to 11 or 12 years (Scott and Crossman, 1973).

Arctic grayling eggs hatch after 11 to 21 days and active feeding begins 3 to 8 days after hatching (Morrow, 1980; Scott and Crossman, 1973). Information regarding the movement of juveniles subsequent to hatching is lacking, but presumably they occupy seasonal habitats similar to those occupied by adults. Sexual maturity can occur as early as 4 years of age, although maturity is more commonly reached at 6 to 9 years of age (Scott and Crossman, 1973).

2.1.2.6 Dolly Varden

Dolly Varden are distributed in Asia from Japan and North Korea north to the Kamchatka and Chukchi peninsulas. In North America, Dolly Varden are found from northern Washington along the Pacific and Arctic coasts to the Mackenzie River in Canada (Mecklenburg et al., 2002; Quinn, 2005). Two forms of Dolly Varden exist that can be distinguished by the number of gill-rakers and vertebrae (Mecklenburg et al., 2002). These two forms, a southern and a northern, are geographically separated by the Alaska Peninsula. Alaskan populations of the northern form range from drainages of Bristol Bay north to the Arctic coast (Mecklenburg et al., 2002). Both anadromous and non-anadromous populations are thought to occur in Bristol Bay drainages (McPhail and Lindsey, 1970). Within the study area, Dolly Varden are present in the NFK, SFK, UT, and KR systems (Chapter 15).

Dolly Varden exhibit a wide variety of life history, migration, and habitat utilization patterns, but some consistencies are found among populations along the Pacific coast of Alaska. All Dolly Varden are iteroparous (spawn multiple times) fall spawners, although northern forms only spawn every 2 to 3 years while southern forms spawn annually (Morrow, 1980; Quinn, 2005). Northern forms reach maturity at 7 to 9 years of age while southern forms reach maturity at 4 to 6 years of age. Spawning occurs from late August through November and redds are usually located in streams with moderately strong currents and water depths greater than 12 inches (30 centimeters). The incubation time for Dolly Varden eggs is approximately 130 days at 8.5°C, and fry emergence takes place 60 to 70 days after hatching (Morrow, 1980).

Following emergence, the behavior of Dolly Varden fry depends largely upon whether the population is anadromous or non-anadromous. In anadromous populations, juveniles remain in rivers or lakes for 3 to 4 years before migrating seaward. Smolt outmigration occurs from early spring through July and, in some systems, a second fall outmigration occurs. Because anadromous adult Dolly Varden overwinter in freshwater habitats after spawning, these adults outmigrate in the spring with the smolts. Time spent at sea is highly variable, ranging from 2 weeks to 7 months. Returns to freshwater may be solely for overwintering or for both overwintering and spawning purposes. Little is known about the migratory patterns of stream-resident (i.e., non-anadromous) populations, but it has been suggested that these fish occupy deep pools in the winter and larger stream reaches in the summer (Morrow, 1980).

The types of habitat used by Dolly Varden can be difficult to characterize because of the diversity of life history and migration patterns exhibited by this species. Stream systems with and without lakes are used by both juveniles and adults for various purposes (Morrow, 1980). For example, Dolly Varden may spawn in streams not associated with a lake, yet overwintering may occur in a stream-lake system. Juveniles also tend to migrate into several different streams after returning to freshwater (Morrow, 1980). Dolly Varden spawn in streams with water temperatures ranging from 5.5°C to 6.5°C and with clean gravel ranging in size from 0.2 to 2 inches (0.6 to 5 centimeters) in diameter. Recently emerged fry occupy the bottoms of pools and eddies (Morrow, 1980).

The freshwater prey of juveniles and adults include many types of insects, spiders, and annelids, in addition to snails, clams, fish eggs, and small fish. Fry consume various items including mayfly and midge larvae, winged insects, and small crustaceans (Morrow, 1980).

2.1.2.7 Rainbow Trout

Rainbow trout are native to the Kamchatka Peninsula in Asia and from northwest Mexico to the Kuskokwim River, Alaska, in North America (Mecklenburg et al., 2002). This species has also been widely introduced throughout the world, including in interior Alaska near Fairbanks, Big Delta, and Summit Lake (Morrow, 1980). The distribution of native populations in Alaska extends along the coast from the Alaska panhandle north to the Kuskokwim River and west to the Port Moller region of the Alaska Peninsula (Mecklenburg et al., 2002). Within the study area, rainbow trout are present in the NFK, SFK, UT, and KR systems (Chapter 15).

While both anadromous and non-anadromous populations occur throughout most of their range, only non-anadromous rainbow trout populations occur in the Bristol Bay region (Quinn, 2005). Accordingly, the life history of non-anadromous rainbow trout is described herein. Adult rainbow trout typically stay relatively close to their natal streams and, consequently, spawning migration distances are usually short (only a few miles; Morrow, 1980). Spawning occurs in the spring and generally takes place in May and June when eggs and milt are deposited into redds. Unlike most Pacific salmon, rainbow trout are iteroparous, meaning they may survive to spawn in subsequent years. Repeat spawning is common in resident rainbow trout (Quinn, 2005) and annual spawning may occur for up to 5 consecutive years for some fish (Morrow, 1980). Rainbow trout mature at an age of 3 to 5 years and may live as long as 9 years (Morrow, 1980). Rainbow trout incubation times typically range from 4 to 7 weeks, depending on water temperature. Fry emergence usually occurs between mid-June and mid-August (Morrow, 1980).

Non-anadromous rainbow trout can often be characterized as exhibiting either stream-resident or lake-resident life histories. Lake-resident fish (referred to as adfluvial) enter streams to spawn, but spend much of their life cycle rearing in lake habitats. This is characteristic of the adfluvial rainbow trout of Iliamna Lake that utilize a variety of tributary streams, including the UT, for spawning. Lake-resident fry may quickly disperse to lake habitats after emergence in the stream, or they may remain in the stream for up to 3 years (McPhail and Lindsey, 1970; Scott and Crossman, 1973). Stream-resident fish remain in stream habitats for the duration of their life cycle.

When in rivers and streams, rainbow trout can be commonly found near lake outlets or below waterfalls and rapids (McPhail and Lindsey, 1970). Tributary streams are used as spawning habitat by both stream- and lake-resident populations (Morrow, 1980). Redds are often constructed in fine gravel substrates of riffles adjacent to pools. Preferred spawning and incubation water temperatures are between 10°C and

13°C, and groundwater upwelling and dissolved oxygen concentrations are important in determining egg survival rates (McPhail and Lindsey, 1970; Morrow, 1980). Juveniles from stream-resident populations occupy riffles during the summer months and tend to shift into pools for the autumn and winter months (McPhail and Lindsey, 1970).

2.1.2.8 Other Species

Additional fish species inhabiting at least some portion of the study area include burbot (*Lota lota*), northern pike (*Esox lucius*), sculpin (*Cottus* sp.), stickleback (*Gasterosteidae*), and lamprey (*Lampetra* sp.). While these species are of ecological importance, for purposes of this study they were not considered target species. This study focused on the aforementioned salmonid species, primarily because of their commercial, subsistence, and/or recreational fisheries importance. Northern pike can also represent an important component of subsistence and recreational fisheries, but they typically inhabit low velocity environments such as clear vegetated lakes and quiet pools and backwaters of streams and rivers (Mecklenburg et al., 2002). These lacustrine-like habitats are not as influenced by flow modifications as riverine systems and, therefore, northern pike were not considered as part of the instream flow study.

3. METHODS

The Instream Flow: Main Channel Habitat Study was initiated in 2004, with additional work completed in 2005, 2006, 2007, and 2008. The studies were designed to:

- Describe existing main channel habitats with regard to channel profiles, hydrology, and habitat conditions (e.g., habitat types, substrate, and cover).
- Define species and lifestage specific relationships between stream flow and fish habitat.
- Based on the latter information, estimate the total amounts of available habitat by species and lifestage under baseline flow conditions in the NFK, SFK, UT, and upper portion of the KR.

Chronologically, the study involved completion of the following six steps:

1. Study Planning and Methodology Selection
2. Transect Selection
3. Field Data Collection
4. Habitat Suitability Criteria Curve Development
5. Data Analysis and Modeling
6. Time Series Analysis

3.1 Study Planning and Methodology Selection

As noted above, this study was initiated in 2004, with additional work completed in 2005 through 2008. During this period, the study has evolved from a reconnaissance level analysis completed in 2004, to a more directed analysis completed during 2005 through 2007 (focused on identifying and modeling representative habitat types within each stream system), to a more detailed analysis of specific areas in

2008. Planning activities have varied by year, but generally all involved identifying transect sites to be measured, reviewing available hydrology and selecting target flows to be measured, and scheduling field data collection.

Because the total distance from the Pebble Deposit to Bristol Bay along the three major river pathways is 228, 232, and 150 miles (including the 33 miles to transit Iliamna Lake) for the NFK, SFK and UT drainages, respectively, one of the initial planning tasks focused on determining the lower boundary of the instream flow study area. This involved reviewing existing hydrology for each basin and defining the approximate points in each system below which flow effects are expected to comprise less than 10% of the base flow for that reach. This approach is essentially the reciprocal of that suggested by Bovee (1982) of placing segment boundaries wherever depletion or accretion changes the average base flow by more than 10%. The analysis indicated that the point of low impact would occur in the lower reaches (Reach A respectively) of all three systems and would be even less in the mainstem KR. As a result, the boundary of the instream flow study area was conservatively set to include the entire lengths of the NFK (36 miles), SFK (40 miles) and UT (39 miles) systems, and a 10-mile segment of the upper KR.

In terms of the selection of an instream flow methodology, there are many different methods and models that have been developed and used for quantifying fish habitat and formulating instream flow recommendations for aquatic biota. Wesche and Rechard (1980), Morhardt (1986), Stalnaker and Arnette (1976), the proceedings of the Symposium on Instream Flow Needs (Orsborn and Allman eds., 1976), Lewis et al. (2004), and the Instream Flow Council (Annear et al., 2004; Locke et al., 2008) describe and review most of the instream flow methods commonly applied today. Each of the methods has specific strengths and weaknesses that must be considered when selecting a particular instream flow methodology for application on a project. For the Pebble Project, the selection of a specific instream flow methodology was based on consideration of the following criteria that were deemed important in defining baseline conditions and evaluating potential project effects:

- The predictive capability of the method or model to extrapolate results over a range of flows.
- The ability of the method to depict flow and habitat changes incrementally.
- The applicability of the methodology to different fish species, including anadromous and resident salmonids.
- The number of lifestages considered in the method (e.g., spawning, fry, juvenile, and passage).
- The biological soundness of the methodology results (i.e., habitat-flow relationship curves and criteria that relate directly to the fish species present in the NFK, SFK, UT and KR systems).
- The sensitivity of the method/model output to the individual user (i.e., ability to control bias).
- The reproducibility of results, both field data collection and modeling.
- The acceptability of the method/model by state and federal agencies in Alaska.

Consideration of the above criteria and the size and complexity of the project resulted in the selection and use of the U.S. Fish and Wildlife Service's Instream Flow Incremental Methodology (IFIM) and its associated Physical Habitat Simulation (PHABSIM) computer programs (Bovee, 1982; Milhous et al., 1984; Bovee et al., 1998; and Stalnaker et al., 1995) for collecting and analyzing habitat and flow data and developing habitat-flow relationships. This was because the IFIM/PHABSIM methodology allows for

the derivation of species and lifestage specific habitat-flow relationships and provides a mechanism for evaluating the effects of incremental changes in flow. Application of the IFIM/PHABSIM method is described below and followed the general procedures outlined in Bovee (1982), Bovee et al. (1998) and Milhous et al. (1984); field work was completed based on methods patterned after those presented in Trihey and Wegner (1983).

3.2 Transect Selection

Field studies first centered around establishing a series of transects (lines extending across the channel) within each stream located at different habitat types, such as riffle, run, pool, glide, cascade, and island complexes (Bain and Stevenson, 1999). Then habitat characteristics (consisting of depth, mean column velocity, substrate type and/or cover) were measured at intervals across the transects at different flows.

Transect locations were based, in part, on the results of field reconnaissance surveys, habitat mapping surveys of selected stream segments completed in 2005 and 2007 that defined habitat types within those segments, and reviews of topographic maps and remote sensing data and imaging. A more detailed habitat mapping exercise was completed for each of the three project streams in 2009, in which mesohabitat types were defined and spatially located on Geographic Information System (GIS) layers. However, that habitat mapping was not used for transect selection but rather for transect weighting purposes (see Section 3.5.3.1).

Over the 5 years of study, two strategies were applied in selecting transects: an extensive approach used during the studies conducted from 2004 to 2007, and an intensive approach during the 2008 study. The two approaches resulted in the establishment of a total of 138 transects, as described below.

Transect placement during the 2004 to 2007 studies was designed to capture representative habitat types within reaches spanning the entire lengths of the mainstem NFK, SFK, and UT, the upper segment of KR, and one of the major tributaries (UT 1.190) of the UT, as follows:

- The 2004 transects were selected based on professional judgment to represent various habitat types within typical reach habitats, resulting in 36 transects—10 (NFK), 10 (SFK), 11 (UT), and 5 (KR).
- The 2005 transects were selected based on a stratified- random selection process that focused on sampling habitat types within different reaches, resulting in 48 transects—10 (NFK), 17 (SFK), 15 (UT), and 6 (Tributary UT 1.190).
- The 2007 transects were also selected based on a stratified-random selection process, resulting in eight transects—1 (NFK), 1 (SFK), and 6 (UT).

In 2008, multiple transects were established within targeted areas of each stream (identified during an aerial helicopter survey) that contained important habitat features such as areas of known spawning. Transect placement at these sites was based on capturing representative habitat types (e.g., pool, riffle, run, etc.) that comprised such features. There were 46 transects established in 2008:14 (NFK), 3 (Tributary NFK 1.190), 12 (SFK), 6 (Tributary SFK 1.190), and 11 (UT).

During the data review process, several issues were identified on a subset of the transects that would potentially complicate the model calibration process. The issues included, primarily, changes in

streambed elevations and profiles over time and between field surveys, and development of inconsistent flow (Q) versus water surface elevation (WSE) rating curves. A total of 21 transects distributed as follows: eight transects in the NFK, three transects in the SFK, nine transects in UT (including one on UT 1.190), and one transect on KR, had one or both of these issues. As a result, the 21 transects were re-established in early June 2010 and will be surveyed under three flow conditions. Hydraulic models will be developed during the fall of 2010. Therefore, the analysis presented in this report pertains to 71 of the 92 transects established in 2004, 2005, and 2007 and the 46 transects established in 2008, for a total of 117 transects (Table 3). The distribution of these transects consisted of: 30 transects in the NFK (including three transects on NFK 1.190; Figure 2); 43 transects in the SFK (including six transects in SFK 1.190; Figure 4); 40 transects in the UT (including five transects in UT 1.190; Figure 6), and four transects in the KR (Figure 6).

3.3 Field Data Collection

The surveying and collection of field data for the project followed the general procedures described in Bovee (1982) and Trihey and Wegner (1983). During all years of the study, field data were recorded in waterproof survey books or on field data forms. All data were reviewed prior to departing the sample site to check for accuracy and completeness, and to ensure that all measurements had been properly recorded and were legible prior to departure. Each field book or data sheet was dated and initialed by the field reviewer. After each field effort, all data books were photocopied.

Three distinct flow levels were targeted, corresponding to a high-flow (representing approximately 20 percent exceedence flow), mid-flow (representing the 50 percent exceedence flow), and low-flow (representing approximately the 80 percent exceedence flow). These flow levels typically occurred in June, July, and August, respectively, but varied by year and associated runoff and precipitation patterns. In some years, it was not possible to measure three distinctly different flows, in which case supplemental measurements were made the following year to capture the needed flow condition. The collection of transect hydraulic and habitat data at the respective transects occurred from 2005 to 2008. Although 36 transects were established in 2004, hydraulic data were not collected at these transects until 2005.

A crew of two or three individuals, experienced in IFIM/PHABSIM field surveying, data collection, and modeling, conducted the fieldwork. The following data were recorded at each transect:

- Site name, transect number, crew members, and sampling date.
- Velocity meter serial number, propeller assembly, and calibration number.
- Water surface elevations (WSEs)—measured to the nearest 0.01 ft at three locations in the channel: near left water edge, center of channel, and near right water edge (note: in some high flow conditions, only one side of the channel was surveyed due to high velocities and safety concerns).
- Photographs—representative photographs were taken of each transect under most of the sampled flow conditions (Attachment 5).

The transect numbering convention adopted for the study followed the format: Year-Stream Name/Reach-Habitat Type—Transect No/habitat type. For example, Transect 07-NFK1-RF1was a transect that was

established in 20(07) within the North Fork Koktuli River (NFK) in Reach (1), within Riffle Habitat (RF) and represented the first (1) riffle transect in that reach.

3.3.1 Transect Setup

The establishment of transects at each sampling location was completed as follows:

- Survey Preparation—All field equipment used for collecting transect data was checked and assembled for use. This included a spin test of calibrated velocity meters, assembly of the top setting wading rod, calibration of Global Positioning System (GPS) unit, and peg testing of the survey level. Stream discharge data for the reach sampled was obtained from nearby flow monitoring gages or direct measurement on the day of the survey.
- Locations of Transects—Transect locations were recorded and mapped in a field book and location coordinates determined using a handheld GPS unit. A wooden lathe containing the number of each transect was positioned on at least one side of the stream and colored survey flagging placed on the lathe and neighboring vegetation to mark the position of each transect.
- Establishment of Site Benchmarks—Permanent surveying benchmarks were established at each site. The benchmarks (e.g., bedrock or boulder point, nail in tree trunk, or rebar pounded firmly into the ground) were placed above the floodplain of the river, and marked with survey flagging. All survey measurements within a site, including headpin and water surface elevations, were referenced to an arbitrary (primary) benchmark elevation of 100.00 feet.
- Establishment of Head Pins, Tail Pins and Working Pins—During the 2004 through 2007 studies, head pins and tail pins were established on both sides of the river (head pins on the left side of the channel and tail pins on the right, looking downstream) so that a line connecting these points would be perpendicular to the main flow of the stream channel. Head pins and tail pins were typically established by driving a 30-inch length of steel rebar into the bank at an elevation above the estimated bank-full flow stage. A survey tape was attached directly to the head pin and tail pin during the collection of instream flow data.

  For the 2008 studies, head pins were established on one side of the river near the start or end point of each transect; these were identified as the left head pin or the right head pin looking downstream. The head pins served as vertical reference for water surface and bed elevation measurements only, and were not used to anchor the survey tape. For this, working pins, consisting of wood stakes, a tree stem, or branch were established directly in line with the head pins (usually within 1 foot) on both sides of the river. The working pins were positioned so that a line connecting these points was perpendicular to the main flow of the stream channel. A survey tape was stretched across the stream channel and connected to the working pins during the collection of instream flow data. Transects that crossed an island often included an intermediate pin, or angle point, on the island—around which the survey tape pivoted. These were installed so that the tape was positioned perpendicular to the main flow of each channel along the transect.
- Survey of Headpin Elevations and Completion of Level Loop—Following the installation of the head and tail pins, a level loop survey was completed to establish pin elevations. The elevation data were obtained using an Automatic Level and stadia rod (0.01-foot accuracy). The level loop was considered accurate if closed to within 0.02 feet of the (primary) benchmark elevation.

Figure 9 presents a schematic illustrating survey techniques and locations of depth, velocity, and substrate measurements for a hypothetical transect.

3.3.2 Hydraulic and Habitat Measurements

Transect depth and velocity measurements were collected at set intervals across each transect under at least three flow conditions (Photo 12). All current meters were calibrated according to the manufacturers' instructions prior to the first field trip and field calibrated during each subsequent trip. The velocity meter serial number, propeller assembly code, and calibration number were noted for each transect surveyed.

Intervals were established so that the flow between any two intervals (cells) did not exceed 10% of the total flow in the channel or a minimum of 20 cells. The following data were collected at vertical stations (intervals) across each transect:

- Water Depth (to nearest 0.10-feet in 2005 through 2007 studies; and nearest 0.05 feet in 2008)—depths were measured using either a 4-foot or 6-foot top setting rod, depending on water depth;
- Mean Column Water Velocity (to nearest 0.01 feet per second)—velocities were measured using a calibrated Swoffer Model 2100, Marsh McBirney Model 2000, or Price AA velocity meter. For depths less than 2.5 feet, velocities were measured at 6/10ths depth in the water column. For depths greater than 2.5 feet, velocities were measured at 2/10ths and 8/10ths depth in the water column.
- Substrate—visual classification of substrate characteristics was made for each cell, based on a modified Wentworth Scale (Table 4). The identification of substrate composition was completed during the mid-flow sampling dates; however, when new interval locations were added during subsequent sampling periods (as was necessary for maintaining the interval location criteria given changing flow conditions), substrate data were collected at the same time the interval point was added.
- Cover—visual assessment of the presence of bank cover, object cover (e.g., overhanging boulders), and woody debris cover was recorded for each cell (Table 5).

All data were reviewed prior to departing the sample site to ensure that all necessary data were collected and legible. After each field effort, field notes were photocopied, checked, and entered into computer data files.

3.4 Habitat Suitability Criteria Curve Development

HSC curves are a required element for defining habitat-flow relationships. HSC reflect species and lifestage use and preference for selected habitat parameters (depth, velocity, and substrate; Bovee, 1982, 1986). Depending on the extent of data available, HSC curves can be developed from the literature (Category 1 curves), or from physical and hydraulic measurements made in the field over species microhabitats (Category 2 curves). When adjusted for the availability of habitat, the curves may more accurately reflect species preference (Category 3 curves) as described in Bovee (1986).

3.4.1 HSC Data Collection Methods

For the Pebble Project, a combination of methods were used for deriving HSC criteria including both literature information and HSC curves from other studies, as well as collecting and analyzing site-specific data for various target species and lifestages. The collection of site-specific data focused on collecting data related to spawning habitat use, and juvenile (and adult—for resident salmonids) rearing habitat use. The HSC data collected included microhabitat data (depth, velocity, and substrate data) over redds and at observed locations of juvenile and adult habitat use (Photo 13). Site-specific microhabitat use data were collected at redd locations in 2005, 2006, and 2008, and at observed fish locations in 2007 and 2008.

The dates of both the redd and juvenile/adult surveys were based, in part, on a generalized periodicity chart that depicts the timing of habitat use of anadromous and resident salmonid species for different lifestages within the three drainages (Table 1). The periodicity information was based on available data at the time of its development and was used to assist in determining approximate dates of field surveys. The periodicity chart will be updated as new information is obtained. Additional details concerning the development of HSC curves for the project are presented in Attachment 1.

The survey methods used for collecting the HSC field data are briefly summarized below; additional details are provided in Attachment 1.

3.4.1.1 Redd Surveys

Redd (spawning nest) surveys were completed in 2005, 2006, and 2008 in the NFK, SFK, and UT watersheds (Photo 14). These surveys were used to locate and collect physical and hydraulic measurements over active redds of target fish species. To maximize the number of redds found, sample site selection was based on redd abundance and distribution information obtained from aerial observations, including those made as part of salmon escapement studies. For 2005 and 2006, sampling was timed with Chinook and sockeye salmon spawning, such that sampling occurred in late July 2005, and in early August 2005 and 2006. All 2005 redd sampling occurred in the NFK and SFK, while sampling efforts for 2006 included the NFK, SFK, and UT. In early August 2008, redds were measured opportunistically in the NFK, SFK, and UT in conjunction with the low-flow sampling period. Surveys during this period targeted Chinook, chum, and sockeye salmon. Additional surveys were completed in mid-September 2008 and targeted coho salmon spawning in the NFK, SFK, and UT.

All redd surveys were conducted by walking the stream channel in an upstream direction, and identifying the location of newly constructed redds. Several parameters were recorded at each redd location (Table 6). Species, depth, velocity, and substrate were recorded for all sampled redds in all years, as follows:

- Species was determined by direct observation of fish use of a redd, or by direct observation of fish presence in the vicinity of a redd.
- In 2005 and 2006, water depth and velocity were measured at the upper edge, left and right edges, and center of each redd. In 2008, depth and velocities were measured at the upstream edge of each redd, an area reflective of conditions existing prior to redd construction. Depth measurements were recorded to the nearest 0.1-foot using a top-setting rod. Mean velocity measurements were made to the nearest 0.01 feet per second using a Swoffer Model 2100, Marsh McBirney, or Price AA current meter.

- In 2005 and 2006, substrate data were collected at a subset of the redds sampled. In 2005, primary (i.e., dominant), secondary, and tertiary substrates were recorded. Substrate data for 2006 followed the same ordination, but extended to the quaternary and quinary levels. Substrate classifications were made using a modified Wentworth Scale (Wentworth, 1922).
- In 2008, the dominant and subdominant substrate types, and percent composition of the dominant type, were recorded. Redd dimensions (i.e., pit depth, tail depth, length, upper width, middle width, and lower width) were recorded using procedures described in Reiser and White (1981).

3.4.1.2 Juvenile/Adult Snorkel Surveys

Snorkel surveys were completed by a team of two or three fish biologists to obtain observations of juvenile and adult habitat use (Photo 15). The surveys were conducted in an upstream direction and consisted of visually locating and marking (with a colored weight) positions of juvenile or adult fish, and subsequently collecting measurements of water depth (top setting rod), mean column velocity (Swoffer Model 2100, Marsh McBirney, or Price AA current meter), and substrate/cover associations. Only fish holding over a fixed position were included in the microhabitat survey. The snorkel surveys were completed from June 21 to July 19 in 2007, and from August 18 to August 22 in 2008.

3.4.2 Developing HSC Curves

The HSC data from each stream were organized by species and lifestage, entered into commercially-available spreadsheets, and subsequently checked for data entry accuracy. Frequency distributions were then generated for mean velocity, depth, and substrate type for each species and then normalized. For species/lifestages for which 20 or more observations were collected, the frequency distribution of the field observations was then converted to suitability by scaling the distribution between 0 and 1 (utilization values divided by the maximum value observed). The resulting curves were inspected and visually adjusted, in part to smooth out sharp breakpoints, and in the case of depth, extend the range of the curve to reflect a non-limiting condition.

3.5 Data Analysis and Modeling

The data from all 5 years of study were subjected to a quality assurance/quality control review, and were then used in developing hydraulic models for each of the transects that were linked with HSC criteria for the different target species and lifestages to generate habitat-flow relationships. These individual transect specific habitat-flow relationships are presented in Attachment 2. These relationships were used, in combination with results from habitat mapping and reach-specific hydrology, to generate habitat area versus flow relationships on a reach basis, as well as habitat time series and habitat duration curves.

3.5.1 Data Entry and Quality Assurance/Quality Control

Data from all 5 years of study were compiled and subjected to a rigorous quality control review relative to their adequacy for use in developing valid, reliable hydraulic models. The review included an evaluation of field notes and survey data including checks of level loops, cross-sectional data entries (i.e., water depth, velocity, substrate), and water survey elevation data. A line-by-line comparison was made of field data measurements with the computer data file entries. Cross-sectional profiles were plotted and reviewed to determine whether bed elevations had changed between survey dates (see Attachment 3). In addition,

transect photographs were assembled, labeled, and reviewed to provide a visual comparison of flow conditions (Attachment 5). The review process resulted in the development of transect-specific data sets that were used in the development and calibration of hydraulic models.

3.5.2 Hydraulic Modeling

The data resulting from the review process were analyzed using the U.S. Fish and Wildlife Service (USFWS) microcomputer software PHABSIM (DOS Version 2.1). Based on channel morphology, the most appropriate computer simulation model (i.e., IFG4, MANSQ, and WSP) was selected to develop stage-discharge relationships for the various transects. Details of all calibration steps were documented and are provided in Attachment 4. Hydraulic modeling generally included the following steps:

- Raw field data were entered into Excel spreadsheets, reviewed, and reduced into a form ready for creation of hydraulic data decks. Data entry errors were identified, noted in a copy of the field notebook, and corrected. These computer spreadsheets were then used to generate hydraulic data input files for the PHABSIM hydraulic simulation program, IFG4.
- The IFG4 data files were checked for any errors and erroneous field measurements using the REVI4 and CKI4 computer programs.
- Stage:discharge relationships were developed using one or more simulation models. An initial stage:discharge calibration was conducted using the IFG4 model. Depending upon the hydraulic characteristics of a given transect, the final stage:discharge relationship was developed using one of three methods:
  - A log-log regression method (i.e., IFG4, rating curve developed using the program STGQS4).
  - A channel geometry and roughness method (rating curve developed using the Manning's Equation based program MANSQ).
  - A step-backwater method (rating curve developed using the program WSP).
- Velocities across each transect were calibrated to provide a realistic distribution of mean column velocities across the channel for the entire range of flows employed in habitat simulations.

During the hydraulic model calibration process, it was found that for 21 of the original 92 transects additional data would be useful for refining the calibrations. Therefore, the analyses presented in this report pertain to 71 of the 92 transects established in 2004, 2005, and 2007 and the 46 transects established in 2008.

3.5.3 Habitat Modeling, Habitat Mapping, and Habitat Time Series

Output from the hydraulic modeling was used in conjunction with the draft HSC criteria to simulate habitat conditions over a range of flows. The range nominally represented about 0.4 of the lowest field measured flow and 2.5 times the highest measured flow. Habitat simulations were conducted using the HABTAV habitat simulation modeling program, which uses velocities obtained from the hydraulic model output files for habitat area calculations (Milhous et al., 1989).

Weighted usable area (WUA) versus discharge curves were calculated for each target fish species and lifestage for all transects and sites. Individual WUA – flow graphs for each transect by target species and

lifestage are presented in Attachment 2. WUA is a habitat index that combines the quantity and quality of habitat of a given species and lifestage provided over a range of flows. WUA is expressed in units of square feet of habitat area per 1,000 linear feet of stream (Bovee, 1982; Milhous et al., 1989). The WUA versus habitat curves, in combination with the results of habitat mapping for each site and reach hydrology were then used to estimate total habitat areas for each reach (Bovee, 1982) over a range of flow conditions.

Habitat mapping analysis was completed in 2009 to estimate the overall quantity of aquatic habitats available in the NFK, SFK, and UT systems. The mapping effort was completed based on combined field and remote-sensing information and analysis. The field surveys conducted in the mainstem NFK, SFK, and UT in 2005 and 2007 were used to identify and delineate mesohabitat types within selected sample areas. Mesohabitat type definitions were based on Moore et al. (2006) and included run, riffle, pool, backwater, and beaver ponds. These data were used to construct a map of mesohabitat types described during the field surveys.

GIS polygons were subsequently overlaid on and calibrated to a set of 2004 ortho-rectified digital imagery taken of the NFK, SFK, and UT. The polygons were used to expand the habitat maps to unsurveyed portions of each mainstem river. Other available digital data sources included 2004 geo-referenced videography obtained from a low-flying helicopter of the SFK and UT, and 2008 ortho-rectified digital imagery of the UT. These data sources were reviewed to confirm and refine the photo-derived habitat classifications for the SFK and UT. Final mesohabitat types were quantified and detailed habitat maps prepared and used for weighting transects by habitat types, and computing total habitat area versus flow relationships for each study reach.

Habitat area is used to express the total habitat area provided by a specified flow for a given river or segment, and is typically expressed in square feet, acres, or hectares. Habitat area combines the amount of WUA provided among the different instream flow transects in a river reach. The WUA values for each transect were weighted according to the total length of habitat represented by habitat type which the transect(s) represents.

Habitat time series and plots of habitat duration were computed first on an individual transect basis and then based on the plots of habitat area versus flow. Habitat time series are generated by linking the WUA-flow relationships with the biologically relevant period of the reach hydrology. For the Pebble Project, three hydrologic conditions were considered, corresponding to a representative Wet, Average, and Dry water year type. The determination of reach hydrology was based on stream gage data collected within each reach.

The specific process used in developing habitat time series and duration plots for each stream, including transect weighting and habitat mapping, and the determination of baseline hydrology, are described below.

3.5.3.1 North Fork Koktuli River

Transect Weighting and Habitat Mapping

As noted above, the standard output from the PHABSIM model consists of a relationship between WUA of fish habitat and flow for a given species and lifestage. The WUA for a single transect is expressed as

area of fish habitat per 1,000 feet of stream length. To convert this to an actual area, a portion of the stream length must be assigned to the transect. Results of the habitat mapping were used as a guide for assigning stream length to each transect in each of the reaches of the NFK.

Because transect locations had been selected prior to habitat mapping and reach delineations, the habitat composition suggested by the number of transects and their respective habitat types may not exactly match the habitat composition determined from the habitat mapping process noted above. Therefore, a two-step process was used to adjust for this and to determine an appropriate stream length to assign to each transect, as shown in Tables 7 and 8.

For example, in NFK-C, habitat mapping indicated that this reach consists of 41.0% run, 42.7% riffle, 1.8% pool, and 14.5% island complex. Within this reach, at least one or more transects were selected for run, riffle, and island complex habitat, but no transects were selected for pool habitat. Therefore, for transect weighting purposes, habitat percentages were rescaled in proportion to their relative abundance for habitat types represented by transects (Table 7). The adjusted habitat composition for transect weighting was: 41.8% run, 43.4% riffle, and 14.8% island complex.

For each habitat type represented by transects in a given reach, the total adjusted habitat length was shared equally by the transects with the same habitat type (Table 8). For example, the total adjusted habitat represented by riffle habitat in NFK-B was 10,484 feet (3,196 meters). There were four riffle transects in NFK-B: 07-NFK1-RF1, 05-NFK1-RF2, 05-NFK1-RF1, and 04-NFK-RF1. Each of these four transects was assigned a stream length of 2,621 feet (799 meters).

The anadromous portion of Tributary NFK 1.190 was determined to have a length of 26,250 feet (8,001 meters). However, all of the transects on this reach were located near the mouth, where the stream is wider than the upstream end of the anadromous reach. If the WUA were extrapolated to the entire length of the anadromous reach, the habitat area would be overestimated because the stream is narrower at the upstream end. To account for the reduction in width through this reach, the effective reach length was reduced to 25,397 feet (7,741 meters).

Habitat mapping indicated that the anadromous reach of Tributary NFK 1.190 consisted of 26.7% run, 67.2% riffle, and 6.1% pool (total = 100%). Within this reach, there were a total of three transects: one run transect, one riffle transect, and one pool transect; therefore, it was not necessary to rescale the habitat percentages (Table 9). The stream lengths assigned to each of these three transects matched to total stream length assigned to run, pool, and riffle habitat shown in Table 10.

Baseline Hydrology

Baseline hydrology for the NFK for habitat time series analyses was based on daily flows from Water Years 2005 through 2008 (October 1, 2004, through September 30, 2008). Measured and synthesized daily flows for this 4-year period were obtained for the following locations within the NFK Basin:

- Hydrology Gage NK100A—NFK at RM 3.27 (RK 5.27) in NFK-A. This gage is maintained by the USGS (USGS Gage No. 15302250).
- Hydrology Gage NK100A1—NFK at RM 8.5 (RK 13.70) in NFK-B.
- Hydrology Gage NK100B—NFK at RM 22.2 (RK 35.75) in NFK -C.

- Hydrology Gage NK119A—West Fork of Tributary NFK 1.190. Confluence with the NFK at RM 22.7 (RK 36.52) in NFK-C.
- Hydrology Gage NK119B—East Fork of Tributary NFK 1.190. Confluence with the NFK at RM 22.7 (RK 36.52) in NFK-C.
- Hydrology Gage NK100C—NFK at RM 22.8 (RK 36.76) in NFK-D.

Daily flows at these hydrology gages were used to estimate daily flows at IFIM transects on the NFK. Daily flows at IFIM transects were determined from the daily flows at the hydrology gages using drainage area to interpolate.

The range of daily flows in NFK-A, NFK-B, and NFK-C is shown on Figure 10 for the 4-year period extending from October 1, 2004, to September 30, 2008. The ranges of daily flows during this period in each of these reaches were as follows:

- NFK-A—30 to 1,863 cfs.
- NFK-B—25 to 1,273 cfs.
- NFK-C—10 to 1,088 cfs.

Interpolated daily flows at Transect 04-NFK-IC2 are also shown on Figure 10. This transect is located in the NFK at RM 20.9 (RK 33.65) in NFK-C.

Daily flows at Hydrology Gage NK100A (USGS Gage No. 15302250) were used to determine a wet, average, and dry condition for each species and lifestage evaluated in the habitat time series analyses. Results of these analyses are summarized in Table 11 for various lifestages of: Chinook, coho, chum, and sockeye salmon; rainbow trout; Dolly Varden; and arctic grayling. For example, Chinook salmon typically spawn during July and August. Wet, average, and dry conditions for Chinook salmon spawning were determined to be in 2006, 2008, and 2007, respectively, as shown on Figure 11.

Daily flows in Tributary NFK 1.190 were determined from flows measured at Hydrology Gage NK119A. The range of daily flows in Tributary NFK 1.190 between the mouth and Hydrology Gage NK119A (RM 1.18; RK 1.90) is shown on Figure 12 from October 1, 2004, through September 30, 2008.

Analyses were performed to determine a wet, average, and dry condition for each species and lifestage. Results of these analyses are summarized in Table 12 for various lifestages of: Chinook, coho, chum, and sockeye salmon; rainbow trout; Dolly Varden; and arctic grayling. Wet, average, and dry conditions for Chinook salmon spawning in NFK 1.190 were determined to be in 2006, 2005, and 2007, respectively, as shown on Figure 13.

Habitat Time Series and Duration Analysis

Habitat time series and duration were analyzed for each reach of the NFK and for Tributary NFK 1.190 for each target species and lifestage. To illustrate the steps involved in these calculations, Chinook salmon spawning at Transect 05-NFK1-IC1 in NFK-B (RM 9.5; RK 15.33) was selected (Figure 14). There were four steps involved in the process for each transect consisting of the following:

1. Daily flows at the transect location were determined for the period associated with the target species and lifestage under wet, average, and dry conditions.
2. Output from the HABTAV program were converted to a habitat-flow relationship for the transect by applying a stream length.
3. Daily flows from Step 1 were combined with the habitat-flow relationship in Step 2 to determine a daily time series of habitat area under wet, average, and dry conditions.
4. Habitat duration under wet, dry, and average conditions was determined from the daily time series of habitat from Step 3.

The four steps were repeated for each transect in a reach. Daily time series of total habitat area in a reach were determined by summing the habitat areas from all of the weighted transects in the reach. Habitat duration under wet, dry, and average conditions was determined for the reach from the daily time series of total habitat area.

3.5.3.2 South Fork Koktuli River

Transect Weighting and Habitat Mapping

The transect weighting and habitat mapping process for the SFK followed that described for the NFK. As in the NFK, transect locations in the SFK had been selected prior to habitat mapping and reach delineation. Thus, within a given reach, the habitat composition suggested by the number of transects and their habitat type may not exactly match habitat composition from habitat mapping. In this case, the same two-step process described for the NFK was used to determine an appropriate stream length to assign to each transect (Tables 13 and 14). For example, in SFK-A, habitat mapping indicated that this reach consists of 27.2% run, 54.2% riffle, 2.4% pool, and 16.2% island complex. Within this reach, at least one or more transects were selected for run, riffle, and island complex habitat, but no pool transects were selected. Habitat percentages were, therefore, rescaled in proportion to their relative abundance for habitat types represented by transects. The adjusted habitat composition for transect weighting was 27.8% run, 55.6% riffle, and 16.6% island complex.

As in the NFK, for each habitat type represented by transects in a given reach of SFK, the total adjusted habitat length was shared equally by the transects with the same habitat type. For example, the total adjusted habitat represented by island complex habitat in SFK-B was 5,336 feet (1,626 meters; Table 13). There were two island complex transects in SFK-B (04-SFK-IC2 and 05-SFK2-IC1). Each of these two transects was assigned a stream length of 2,668 feet (813 meters; Table 14).

The anadromous portion of Tributary SFK 1.190 was determined to have a length of 22,444 feet (6,841 meters). However, all transects in this reach were located relatively close to the mouth, where the stream is slightly wider than at the upstream end. Therefore, the reach length was adjusted to 19,708 feet (6,007 meters). Habitat mapping indicates that the anadromous reach of Tributary SFK 1.190 consists of 21.7% run, 66.4% riffle, and 11.9% pool. Within this reach, at least one or more transects were selected for run and riffle habitat, but no pool transects were selected. For transect weighting, habitat percentages were rescaled and the adjusted habitat compositions were 24.7% run and 75.3% riffle (Table 15). Each habitat type represented by transects in Tributary SFK 1.190 was shared equally by transects with the same habitat type (Table 16).

Baseline Hydrology

Baseline hydrology for the SFK for the habitat time series analyses was based on daily flows from Water Years 2005 through 2008 (October 1, 2004, through September 30, 2008). Measured and synthesized daily flows for this 4-year period were obtained for the following locations:

- Hydrology Gage SK100A—SFK at RM 0.07(RK 0.11) in SFK-A.
- Hydrology Gage SK100B—SFK at RM 15.5 (RK 24.90) in SFK-B. This gage is maintained by the USGS (USGS Gage No. 15302200).
- Hydrology Gage SK100B1—SFK at RM 18.2 (RK 29.26) in SFK-C.
- Hydrology Gage SK119A—Tributary SFK 1.190. Confluence with the SFK at RM 21.3 (RK 34.28) in SFK-B.
- Hydrology Gage SK100C—SFK at RM 22.3 (RK 35.81 in SFK-C.
- Hydrology Gage SK100F—SFK at RM 34 (RK 54.67 in SFK-D.

Daily flows at these hydrology gages were used to estimate daily flows at each of the SFK transects via drainage area interpolation.

The range of daily flows (for the 4-year period extending from October 1, 2004, to September 30, 2008) in SFK-A, SFK-B, and SFK-C is shown on Figure 15. These ranges were as follows:

- SFK-A—9 to 1,619 cfs.
- SFK-B—zero to 1,260 cfs.
- SFK-C—zero to 548 cfs.

Interpolated daily flows at IFIM Transect 05-SFK2-RN3 are also shown on Figure 15. This transect is located in SFK at RM 18.8 (RK 30.19 in SFK-B.

The daily flows at Hydrology Gage SK100B (USGS Gage No. 15302200) were used to determine a wet, average, and dry condition for each species and lifestage evaluated in the habitat time series analyses for the SFK. Results of these analyses are summarized in Table 17 for various lifestages of: Chinook, coho, chum, and sockeye salmon; rainbow trout; Dolly Varden; and arctic grayling. For example, Chinook salmon typically spawn during July and August. Wet, average, and dry conditions for Chinook salmon spawning were determined to be in 2006, 2008, and 2007, respectively, as shown on Figure 16.

Daily flows in Tributary SFK 1.190 were determined from flows measured at Hydrology Gage SK119A. The range of daily flows in Tributary SFK 1.190 between the mouth and Hydrology Gage SK119A (RM 1.12; RK 1.80) is shown on Figure 17 from October 1, 2004, through September 30, 2008. Analyses were subsequently performed to determine a wet, average, and dry condition (based on Hydrology Gage SK119A) for each species and lifestage evaluated in the habitat time series analyses of Tributary SFK 1.190. Results of these analyses are summarized in Table 18 for various lifestages of: Chinook, coho, chum, and sockeye salmon; rainbow trout; Dolly Varden; and arctic grayling. For example, wet, average, and dry conditions for Chinook salmon spawning in SFK 1.190 were determined to be in 2006, 2005, and 2007, respectively, as shown on Figure 18.

Habitat Time Series and Duration Analysis

Habitat time series and duration were analyzed for the SFK using the same process described for the NFK. There were essentially four steps involved in this process, exemplified for Chinook salmon spawning at Transect 08-SFK1-MS1-TR5 in SFK-A (RM 4.4; RK 7.05), was selected (Figure 19). The four steps consisted of the following:

1. Daily flows at the transect location were determined for the period associated with the target species and lifestage under wet, average, and dry conditions.
2. Output from the HABTAV program were converted to a habitat-flow relationship for the transect by applying a stream length.
3. Daily flows from Step 1 were combined with the habitat-flow relationship in Step 2 to determine a daily time series of habitat area under wet, average, and dry conditions.
4. Habitat duration under wet, dry, and average conditions was determined from the daily time series of habitat from Step 3.

As in the NFK, the four steps were repeated for each transect in a reach. Daily time series of total habitat area in a reach were determined by summing the habitat areas from all of the weighted transects in the reach. Habitat duration under wet, dry, and average conditions was determined for the reach from the daily time series of total habitat area.

3.5.3.3 Upper Talarik Creek

Transect Weighting and Habitat Mapping

As in the NFK, transect locations in the UT had been selected prior to habitat mapping and reach delineation and were therefore adjusted (Tables 19 and 20). For example, in UT-C, habitat mapping indicated that the reach consisted of 64.6% run, 20.4% riffle, 1.5% pool, and 13.5% island complex. Within this reach, at least one or more transects were selected for run, riffle, and island complex habitat, but no pool transects were selected. For transect weighting purposes, habitat percentages were rescaled and adjusted to 65.6% run, 20.7% riffle, and 13.7% island complex (Table 19).

As in the NFK and SFK, the total adjusted habitat length was shared equally by the transects with the same habitat type. For example, the total adjusted habitat represented by island complex in Reach UT-C was 3,570 feet (1,088 meters). There were two island complex transects in Reach UT-C (05-UTC1-IC1 and 04-UTC-IC2) and therefore each transect was assigned a stream length of 1,785 feet (544 meters; Table 20).

A slightly different approach was used for transects for Tributary UT 1.190. The anadromous portion of this reach was determined to have a total length of 10,653 feet (3,247 meters). Although habitat mapping indicated that the reach was entirely riffle habitat, as shown in Table 21, the six transects initially selected in this reach were comprised of five representing riffle and one run habitat. Therefore, the adjusted habitat composition was determined to be 16.7% run and 83.3% riffle. However, of the five riffle transects initially selected, one was omitted during the quality assurance/quality control (QA/QC) process and is undergoing further field data collection. The entire adjusted run habitat stream length (1,776 feet/ 541

meters) was, therefore, assigned to the single run transect, and the entire adjusted riffle habitat stream length (8,878 feet/ 2,706 meters) was shared equally by the remaining four riffle transects, (Table 22).

Baseline Hydrology

Baseline hydrology for UT for habitat time series analyses was based on daily flows from Water Years 2005 through 2008 (October 1, 2004, through September 30, 2008). Measured and synthesized daily flows for this 4-year period were obtained from the following locations within the UT Basin:

- Hydrology Gage UT100APC3—UT at RM 1.4 (RK 2.24) in UT-A.
- Hydrology Gage UT100APC2—UT at RM 6.1 (RK 9.85) in UT-B.
- Hydrology Gage UT100APC1—UT at RM 6.1(RK 9.85) in UT-B.
- Hydrology Gage UT100B—UT at RM 15.2 (RK 24.50) in UT-C. This gage is maintained by the USGS (USGS Gage No. 15300250).
- Hydrology Gage UT119A—Tributary UT 1. Confluence with the UT at RM 15.4 (RK 24.74) in UT-C.
- Hydrology Gage UT100C—UT at RM 18.2 (RK 29.31) in UT-D.
- Hydrology Gage UT100C1—UT at RM 23.4 (RK 37.64) in UT-E.
- Hydrology Gage UT100C2—UT at RM 27.7 (RK 44.63) in UT-E.
- Hydrology Gage UT135A—Tributary UT 1.350. Confluence with the UT at RM 28 (RK 45.05) in UT-E.
- Hydrology Gage UT100D—UT at RM 32.1 (RK 51.62) in UT-F.
- Hydrology Gage UT100E—UT at RM 37.3 (RK 59.97) in UT-G.

Daily flows at these hydrology gages were used to estimate daily flows at specific transects as determined via interpolation of drainage area.

The range of daily flows in UT-B through UT-F are shown on Figure 20 (for the 4-year period extending from October 1, 2004, to September 30, 2008) and were as follows:

- UT-B—98 to 1,506 cfs.
- UT-C—62 to 1,202 cfs.
- UT-D—39 to 1,025 cfs.
- UT-E—13 to 609 cfs.
- UT-F—4 to 325 cfs.

Interpolated daily flows at IFIM Transect 05-UTC3-RN2 are also shown on Figure 20. This transect was located on the UT at RM 32.3 (RK 52.01) in UT-F.

Daily flows at Hydrology Gage UT100B (USGS Gage No. 15300250) were used to determine a wet, average, and dry condition for each species and lifestage evaluated in the habitat time series analyses of

UT. Results are summarized in Table 23 for various lifestages of: Chinook, coho, chum, and sockeye salmon; rainbow trout; Dolly Varden; and arctic grayling. For example, sockeye salmon typically spawn from July through September. Wet, average, and dry conditions for sockeye salmon spawning were determined to be in 2006, 2005, and 2007, respectively (Figure 21).

Daily flows in Tributary UT 1.190 were determined from flows measured at Hydrology Gage UT119A. Drainage area was used to calculate flows from the mouth to RM 1.54 (RK 2.48), where the most upstream transect (Transect 05-UT190-RF5) was located. The range of daily flows in this reach is shown on Figure 22 from October 1, 2004, through September 30, 2008. Interpolated daily flows at Transect 05-UT190-RN1 are also shown on Figure 22. This transect is located on Tributary UT 1.190 at RM 0.8 (RK 1.35).

Analyses were performed to determine a wet, average, and dry condition for each species and lifestage evaluated in the habitat time series analyses of Tributary UT 1.190. Results of these analyses are summarized in Table 24 for various lifestages of: Chinook, coho, chum, and sockeye salmon; rainbow trout; Dolly Varden; and arctic grayling. For example, wet, average, and dry conditions for sockeye salmon spawning in Tributary UT 1.190 were determined to be in 2005, 2008, and 2007, respectively, as shown on Figure 23.

Habitat Time Series and Duration Analysis

Habitat time series and duration were analyzed for the UT using the same process described for the NFK and SFK. There were essentially four steps involved in this process, exemplified for sockeye salmon spawning at Transect 04-UTC-RN1 in UT-C (RM 14.8; RK 23.75) (Figure 24). These four steps consisted of the following:

1. Daily flows at the transect location were determined for the period associated with the target species and lifestage under wet, average, and dry conditions.
2. Output from the HABTAV program were converted to a habitat-flow relationship for the transect by applying a stream length.
3. Daily flows from Step 1 were combined with the habitat-flow relationship in Step 2 to determine a daily time series of habitat area under wet, average, and dry conditions.
4. Habitat duration under wet, dry, and average conditions was determined from the daily time series of habitat from Step 3.

The four steps were repeated for each transect in a reach. Daily time series of total habitat area in a reach were determined by summing the habitat areas from all of the weighted transects in the reach. Habitat duration under wet, dry, and average conditions was subsequently determined for the reach from the daily time series of total habitat area.

3.5.3.4 Mainstem Koktuli River

Transect Weighting and Habitat Mapping.

The standard output from the PHABSIM model consists of a relationship between WUA and flow for a given species and lifestage. The WUA for a single transect is expressed as area of fish habitat per 1,000

feet of stream length. To convert this to an actual area, a portion of the stream length must be assigned to the transect. The total length of the KR that was analyzed extended from the most downstream transect (RM 15.4; RK 24.85) to the confluence of the North Fork Koktuli River and South Fork Koktuli River (RM 28.8; RK 46.42), a total length of 70,768 feet (21,570 meters).

Habitat mapping was not performed for the KR. Therefore, the habitat composition, reflected by the number and habitat types of the transects selected in this reach, was used to determine stream lengths to assign to each transect. Ten transects were initially (2004) selected in this reach. These 10 transects consisted of three runs, three riffles, two pools, and two island complexes. Thus, the habitat compositions were initially classified as 30.0% run, 30.0% riffle, 20.0% pool, and 20.0% island complex. Of the 10 transects that were initially selected, six were omitted during the QA/QC process. The remaining four transects included one run, two riffles, and one island complex. The adjusted habitat composition was 37.5% run, 37.5% riffle, and 25.0% island complex (Table 25).

For each habitat type represented by the transects in the KR, the total adjusted habitat length was shared equally by the transects with the same habitat type. For example, the total adjusted habitat represented by riffle habitat in this reach was 26,538 ft (8,089 meters). There were two riffle transects in this reach (04-MSK-RF2 and 04-MSK-RF1); therefore, each of these was assigned a stream length of 13,269 feet (4,044.5 meters; Table 26).

Baseline Hydrology

Baseline hydrology for the Koktuli River for habitat time series analyses was based on daily flows from Water Years 2005 through 2008 (October 1, 2004, through September 30, 2008). Synthesized daily flows were based on data provided for the following locations:

- Confluence of the North and South Forks of the Koktuli River.—KR at RM 28.8 (RK 46.42).
- Transect 04-MSK-RF2—The most downstream transect on the KR at RM 15.4 (RK 24.85).

Daily flows at these hydrology gages were used to estimate daily flows at transects on the KR. Daily flows at each transect were determined via interpolation of drainage area.

The range of daily flows in the KR (4-year period extending from October 1, 2004, to September 30, 2008) is shown on Figure 25. The range of daily flows during this period extended from 103 to 4,350 cfs. Interpolated daily flows at Transect 04-MSK-RF1 (located at RM 19.9 / RK 31.98) are shown on Figure 25.

Synthesized daily flows in the KR at the confluence of the NFK and SFK were used to determine a wet, average, and dry condition for each species and lifestage evaluated in the habitat time series analyses (Table 27). For example, Chinook salmon typically spawn during July and August. Wet, average, and dry conditions for Chinook salmon spawning in the KR were determined to be in 2006, 2008, and 2007, respectively, as shown on Figure 26.

Habitat Time Series and Duration Analysis

Habitat time series and duration were analyzed for the KR using the same process described for the NFK, SFK, and UT. There were essentially four steps involved in this process, exemplified for Chinook salmon

spawning at Transect 04-MSK-RF2 in the KR (RM 15.4; RK 24.85), was selected (Figure 27). These four steps consisted of the following:

1. Daily flows at the transect location were determined for the period associated with the target species and lifestage under wet, average, and dry conditions.
2. Output from the HABTAV program were converted to a habitat-flow relationship for the transect by applying a stream length.
3. Daily flows from Step 1 were combined with the habitat-flow relationship in Step 2 to determine a daily time series of habitat area under wet, average, and dry conditions.
4. Habitat duration under wet, dry, and average conditions was determined from the daily time series of habitat from Step 3.

The four steps listed above were repeated for each transect in a reach. Daily time series of total habitat area in a reach were determined by summing the habitat areas from all of the weighted transects in the reach. Habitat duration under wet, dry, and average conditions was determined for the KR reach from the daily time series of total habitat area.

4. HABITAT MODELING

This section presents the results of the habitat modeling and time series analysis completed for each of the four study basins, and organizationally begins with the NFK, followed by the SFK, UT, and KR. Within each basin, results are presented from the lower (e.g., NFK-A) to upper (e.g., NFK-C) modeled mainstem reaches; tributary reaches (e.g., NFK 1.190) are presented last. The results focus on the total habitat area versus flow relationships, because these provide reach-scale estimates of the total amount of habitat for a given species and lifestage available under different flow conditions (see Attachment 2 for individual transect results). For convenience, the results are presented graphically—both as numerical estimates of habitat (expressed in acres), as well as normalized estimates (expressed as a percent of maximum habitat area). The former are useful for comparing the relative amounts of habitat provided for a given species and lifestage under different flow conditions, while the latter are useful for comparing overall habitat-flow response dynamics. The percent of maximum habitat corresponding to specific flows are also presented in tabular format.

In addition, results of the time series analysis are presented graphically by reach in terms of the total habitat area that would occur on a daily basis during the individual species and lifestage periodicities identified in Table 1. Also presented graphically as part of the time series analysis, are habitat duration curves that depict the availability (presented as a # exceedence value) of habitat for a given species and lifestage. Lastly, to compare the amounts of habitat that would occur under a Wet, Average , and Dry year, the average habitat area available on a daily basis in each reach is presented in tabular format for each water year type by species and lifestage. The time series and habitat duration results serve to characterize the baseline conditions of the main channel habitats on a temporal basis relative to specific biologically relevant periods of time, e.g. spawning, juvenile rearing, adult rearing, etc. The results will be especially useful for evaluating potential project induced changes to the existing hydrology of each system and how such changes may affect the amounts of habitat under different water year types (i.e., Wet, Average and Dry).

Results of the habitat area versus flow relationships and time series analysis are presented for each reach and for each of the following species: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. Organizationally, results for anadromous salmonids are presented separately from those for non-anadromous salmonids. Habitat area versus flow relationships are provided for both spawning and juvenile rearing habitat for all species, whereas relationships for adult rearing are only provided for the non-anadromous salmonid species. One exception is that habitat area versus flow relationships were not derived for juvenile chum salmon rearing, because of the short residence time of juvenile chum salmon in the study area.

4.1 North Fork Koktuli River

4.1.1 Reach NFK-A

Modeling results for NFK-A are presented for Chinook, chum, coho, and sockeye salmon, as well as arctic grayling, Dolly Varden, and rainbow trout. All of these species have been documented in this reach (Table 2).

4.1.1.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for NFK-A indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (240 cfs provides approximately [≈] 25 acres), followed by Chinook salmon (460 cfs provides ≈ 13 acres) and coho salmon (380 cfs provides ≈ 13 acres), and then sockeye salmon (270 cfs provides ≈ 12 acres) (Table 28; Figure 28). Habitat amounts remain relatively high (≈ 90% of maximum) for all four anadromous salmonid species even at flows as low as 290 cfs for Chinook salmon, 140 cfs for chum salmon, 270 cfs for coho salmon, and 170 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for Chinook and coho salmon are generally similar—with coho salmon being slightly higher on the ascending limb of the curve and Chinook salmon slightly higher on the descending limb. Likewise, the relationships for chum and sockeye salmon are similar, although greater for chum salmon on the ascending limb of the curve.

The habitat - flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for NFK-A peak at flows of 420 cfs (provides ≈ 25 acres), 320 cfs (provides ≈ 28 acres), and 270 cfs (provides ≈ 22 acres) respectively (Table 29; Figure 28). However, flows as low as 290 cfs for arctic grayling, 210 cfs for Dolly Varden, and 190 cfs for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

For anadromous salmonids, the amount of juvenile rearing habitat provided for NFK-A across the range of modeled flows was greatest for coho salmon, followed by Chinook salmon, and then sockeye salmon (Figure 29). For non-anadromous salmonids, the amount of habitat provided at most flows (i.e., greater than 150 cfs) was greatest for arctic grayling, followed by rainbow trout, and then Dolly Varden. Unlike spawning habitat, the habitat-flow relationship for juvenile anadromous and non-anadromous rearing habitat was generally not clearly defined by an ascending limb, peak, and descending limb. Rather, for

most species, there was a broad range of flows at which 70% or more of the maximum spawning habitat would be provided (Table 28; Table 29; Figure 29).

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for NFK-A indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (153 cfs provides ≈ 14 acres), followed by Dolly Varden (45 cfs provides ≈ 10 acres) and then arctic grayling (460 cfs provides ≈ 6 acres) (Table 29; Figure 30). These relationships show three different trends. Habitat area for arctic grayling generally increases as flows increase, but the curve flattens out beyond 200 cfs. For Dolly Varden, habitat area is maximized at the lowest modeled flow and decreases at higher flows, before flattening out around 200 cfs. In contrast, the curve for rainbow trout is characterized by a steep ascending limb with a distinct maximum and slowly descending limb at higher flows.

4.1.1.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for NFK-A, as determined under an average water year type, are presented for all target species on Figure 31 (spawning habitat) and Figure 32 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 33. In addition, Table 30 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types. The habitat time series depicts how the amounts of habitat can change on a daily basis given representative changes in hydrology that have occurred in the NFK-A under wet, average and dry conditions.

4.1.2 Reach NFK-B

Modeling results for NFK-B are presented for Chinook, chum, coho, and sockeye salmon, and as well as arctic grayling, Dolly Varden, and rainbow trout. With the exception of rainbow trout, all of these species have been documented in NFK-B (Table 2). However, because rainbow trout have been observed in reaches upstream and downstream of NFK-B, this species also likely inhabits NFK-B and is included in the results.

4.1.2.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for NFK-B indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (150 cfs provides ≈ 18 acres), followed by coho salmon (220 cfs provides ≈ 11 acres), and then Chinook salmon (260 cfs provides ≈ 10 acres) and sockeye salmon (110 cfs provides ≈ 10 acres) (Table 31; Figure 34). Habitat amounts remain relatively high (≈ 90% of maximum) for all four anadromous salmonid species, even at flows as low as 220 cfs for Chinook salmon, 80 cfs for chum salmon, 150 cfs for coho salmon, and 80 cfs for sockeye salmon. When habitats are expressed as percentage of maximum, the relationships for Chinook and coho salmon are generally similar, with coho salmon being slightly higher on the ascending limb of the curve and Chinook salmon slightly higher on the descending limb. Likewise, the relationships for chum and sockeye salmon are generally similar.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for NFK-B peak at flows of 240 cfs (provides ≈ 13acres), 180 cfs (provides ≈ 15 acres), and 90 cfs (provides ≈ 9.2 acres), respectively (Table 32; Figure 34). However, flows as low as 129.4 cfs for arctic grayling, 110 cfs for Dolly Varden, and 61.8 cfs for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for NFK-B indicate that the amount juvenile rearing habitat provided at the habitat maximizing flow would be highest for coho salmon (420 cfs provides ≈ 14 acres), followed by sockeye salmon (420 cfs provides ≈ 12 acres) and Chinook salmon (420 cfs provides ≈ 12 acres). For each of these species, the maximum amount of juvenile rearing habitat was provided at the highest modeled flow (Table 31; Figure 35).

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for NFK-B at the habitat maximizing flow would be highest for arctic grayling (420 cfs provides ≈ 18 acres), followed by Dolly Varden (420 cfs provides ≈ 14 acres), and then rainbow trout (420 cfs provides ≈ 8 acres). Like anadromous salmonids, the maximum amount of juvenile rearing habitat in NFK-B for all three non-anadromous species was provided at the highest modeled flow (Table 32; Figure 35).

In general, the habitat - flow relationships for juvenile rearing of all species in NFK-B showed a similar trend, in which habitat area increased asymptotically with flow (Figure 35).

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for NFK-B indicate that the amount of habitat provided at the habitat maximizing flow would be highest for Dolly Varden (420 cfs provides ≈ 15 acres), followed by rainbow trout (160 cfs provides ≈ 11 acres), and then arctic grayling (280 cfs provides ≈ 6 acres; Table 32; Figure 36). Habitat amounts remain relatively high (≈ 90% of maximum) for all three species even at flows as low as 200 cfs for arctic grayling, 340 cfs for Dolly Varden, and 129.4 cfs for rainbow trout. When habitats are expressed as percentage of maximum, the relationships for arctic grayling and rainbow trout are generally similar, increasing with flow until reaching a maximum and then leveling. In contrast, the relationship for Dolly Varden can be characterized as continually increasing with flow up to the maximum modeled flow.

4.1.2.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for NFK-B, as determined under an average water year type, are presented for all species on Figure 37 (spawning habitat) and Figure 38 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 39. In addition, Table 33 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types. The habitat time series depicts how the amounts of habitat can change on a daily basis given representative changes in hydrology that have occurred in the NFK-B under wet, average and dry conditions.

4.1.3 Reach NFK-C

Modeling results for NFK-C are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.1.3.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for NFK-C indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (160 cfs provides ≈ 24 acres), followed by sockeye salmon (150 cfs provides ≈ 16 acres) and coho salmon (200 cfs provides ≈ 16 acres), and then Chinook salmon (225 cfs provides ≈ 13 acres; Table 34; Figure 40). Habitat amounts remain relatively high (≈ 90% of maximum) for all four anadromous salmonid species at flows as low as 180 cfs for Chinook salmon, 90 cfs for chum salmon, 150 cfs for coho salmon, and 110 cfs for sockeye salmon. When habitats are expressed as percentage of maximum, the relationships for anadromous salmonids are generally similar in shape. The habitat area increases at a moderate rate with increasing flow and, after reaching a maximum, gradually decreases. However, this shape is shifted towards lower flows for chum and sockeye salmon and towards higher flows for coho salmon and, in particular, Chinook salmon.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout peak in NFK-C at flows of 225 cfs (provides ≈ 23 acres), 160 cfs (provides ≈ 25 acres), and 170 cfs (provides ≈ 14 acres), respectively (Table 35; Figure 40). However, flows as low as 150 cfs for arctic grayling and 110 cfs for Dolly Varden and rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for NFK-C indicate that the amount juvenile rearing habitat provided at the habitat maximizing flow would be highest for coho salmon (100 cfs provides ≈ 11 acres), followed by Chinook salmon (100 cfs provides ≈ 8 acres), and then sockeye salmon (70 cfs provides ≈ 7 acres; Table 34; Figure 41). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 70 cfs for Chinook salmon, 60 cfs for coho salmon, and 60 cfs for sockeye salmon. At flows beyond roughly 100 cfs, habitat area gradually decreases for Chinook and coho salmon but decreases more rapidly for sockeye salmon.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for NFK-C at the habitat maximizing flow would be highest for arctic grayling (70 cfs provides ≈ 17 acres), followed by Dolly Varden (70 cfs provides ≈ 10 acres), and then rainbow trout (340 cfs provides ≈ 9 acres) (Table 35; Figure 41). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 40 cfs for arctic grayling, 30 cfs or less for Dolly Varden, and 120 cfs for rainbow trout. Habitat-flow relationships for both arctic grayling and Dolly Varden in NFK-C showed similar trends, with habitat area quickly increasing with flow to a maximum and then gradually decreasing at higher flows. In contrast, habitat area for rainbow trout generally increased asymptotically with flow over the modeled range.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for NFK-C indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (140 cfs provides ≈ 14 acres), followed by Dolly Varden (30 cfs provides ≈ 10 acres) and then arctic grayling (240 cfs provides ≈ 8 acres) (Table 35; Figure 42). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 160 cfs for arctic grayling, 110 cfs for Dolly Varden, and 70 cfs for rainbow trout. When habitats are expressed as percentage of maximum, the relationships for arctic grayling and rainbow trout are generally similar in shape, with habitat area increasing with flow until reaching a maximum and then gradually decreasing. In contrast, habitat area for Dolly Varden generally decreases at flows beyond the lowest modeled flow.

4.1.3.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for NFK-C, as determined under an average water year type, are presented for all species on Figure 43 (spawning habitat) and Figure 44 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 42. In addition, Table 36 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types. The habitat time series depicts how the amounts of habitat can change on a daily basis given representative changes in hydrology that have occurred in the NFK-C under wet, average and dry conditions.

4.1.4 Tributary NFK 1.190

Modeling results for Tributary NFK 1.190 are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. Only Chinook salmon, coho salmon, Dolly Varden, and rainbow trout were observed in Tributary NFK 1.190 (Appendix 15.1B). However, because all of the above species have been documented (Table 2) in NFK-C (the reach into which NFK 1.190 flows), they may also inhabit NFK 1.190. Therefore, modeling results for all species are presented.

4.1.4.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for NFK 1.190 indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (70 cfs provides ≈ 1.7 acres), followed by sockeye salmon (85 cfs provides ≈ 0.9 acres) and coho salmon (110 cfs provides ≈ 0.9 acres), and then Chinook salmon (130 cfs provides ≈ 0.8 acres) (Table 37; Figure 46). Habitat amounts remain relatively high (≈ 90% of maximum) for all four anadromous salmonid species at flows as low as 120 cfs for Chinook salmon, 55 cfs for chum salmon, 90 cfs for coho salmon, and 73.9 cfs for sockeye salmon. When habitats are expressed as percentage of maximum, trends are generally similar across species. Habitat increases with flow until a maximum is reached and then, except for Chinook salmon, gradually decreases at higher flows.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for NFK 1.190 peak at flows of 180 cfs (provides ≈ 1.3 acres), 140 cfs (provides ≈ 1.2 acres), and 73.9 cfs (provides ≈ 1.3 acres), respectively (Table 38; Figure 46). However, flows as low as 130 cfs for arctic

grayling, 70 cfs for Dolly Varden, and 65 cfs for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for NFK 1.190 indicate that the amount of juvenile rearing habitat provided for anadromous salmonids at the habitat maximizing flow would be highest for coho salmon (55 cfs provides ≈ 1.4 acres), followed by Chinook salmon (73.9 cfs provides ≈ 1.3 acres), and then sockeye salmon (12.6 cfs provides ≈ 0.9 acres) (Table 37; Figure 47). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 60 cfs for Chinook salmon, 40 cfs for coho salmon, and 10 cfs for sockeye salmon. Unlike results for other lifestages in this reach, the habitat - flow relationships for juvenile rearing do not show clearly defined patterns. Rather, the patterns fluctuate considerably, showing multiple peaks.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for NFK 1.190 at the habitat maximizing flow would be highest for arctic grayling (20 cfs provides ≈ 2.7 acres), followed by rainbow trout (90 cfs provides ≈ 1.5 acres), and then Dolly Varden (5 cfs provides ≈ 1.3 acres) (Table 38; Figure 47). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 12.6 cfs for arctic grayling, 5 cfs or less for Dolly Varden, and 60 cfs for rainbow trout. As with anadromous salmonids, the habitat-flow relationships for non-anadromous salmonids in NFK 1.190 fluctuate considerably, showing multiple peaks.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for NFK 1.190 indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (70 cfs provides ≈ 1.9 acres), followed by Dolly Varden (12.6 cfs provides ≈ 1.5 acres) and then arctic grayling (80 cfs provides ≈ 1.3 acres) (Table 38; Figure 48). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 70 cfs for arctic grayling, 7 cfs for Dolly Varden, and 40 cfs for rainbow trout. When habitats are expressed as percentage of maximum, the relationships for arctic grayling and rainbow trout in NFK 1.190 are roughly similar, with habitat increasing with flow until reaching a maximum and then gradually decreasing. In contrast, habitat for Dolly Varden rapidly reaches a peak at only 12.6 cfs then rapidly decreases at moderate flows before increasing again at flows near the upper end of the modeled range.

4.1.4.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for NFK 1.190, as determined under an average water year type, are presented for all species on Figure 49 (spawning habitat) and Figure 50 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 51. In addition, Table 39 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types. The habitat time series depicts how the amounts of habitat can change on a daily basis given representative changes in hydrology that have occurred in the NFK 1.190 under wet, average and dry conditions.

4.2 South Fork Koktuli River

4.2.1 Reach SFK-A

Modeling results for SFK-A are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.2.1.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for SFK-A indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (130 cfs provides ≈ 41 acres), followed by sockeye salmon (150 cfs provides ≈ 31 acres), Chinook salmon (240 cfs provides ≈ 23 acres), and coho salmon (220 cfs provides ≈ 20 acres) (Table 40; Figure 52). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 160 cfs for Chinook salmon, 90 cfs for chum salmon, 150 cfs for coho salmon, and 120 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in SFK-A are generally similar in shape, where habitat area increases at a moderate rate with increasing flow and, after reaching a maximum, gradually decreases. However, this shape is shifted towards lower flows for chum and sockeye salmon and towards higher flows for coho and Chinook salmon.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for SFK-A peak at flows of 170 cfs (provides ≈ 34 acres), 140 cfs (provides ≈ 41 acres), and 120 cfs (provides ≈ 28 acres), respectively (Table 41; Figure 52). However, flows as low as 130 cfs for arctic grayling, 100 cfs for Dolly Varden, and 70 cfs for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for SFK-A indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for Chinook salmon (170 cfs provides ≈ 9.6 acres), followed by sockeye salmon (80 cfs provides ≈ 7.4 acres), and then coho salmon (120 cfs provides ≈ 6.2 acres) (Table 40; Figure 53). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 110 cfs for Chinook salmon, 80 cfs for coho salmon, and 30 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for coho and sockeye salmon in SFK-A are generally similar, with habitat area initially high at low flows and decreasing to a moderate level at most higher flows. In contrast, habitat area for Chinook salmon is initially moderate at low flows, increases to a maximum as flows increase, and remains at a relatively high level as flows continue to increase.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for SFK-A at the habitat maximizing flow would be highest for arctic grayling (80 cfs provides ≈ 18 acres), followed by rainbow trout (410 cfs provides ≈ 11 acres), and then Dolly Varden (80 cfs provides ≈ 10 acres) (Table 41; Figure 53). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 40 cfs for arctic grayling, 30 cfs or less for Dolly Varden, and 180 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and Dolly Varden in SFK-A are generally

similar, with habitat area initially high at low flows and decreasing to a moderate level at most higher flows. In contrast, habitat area for rainbow trout is initially moderate at low flows, increases to a maximum as flows increase, and remains at a relatively high level as flows continue to increase.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for SFK-A indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (180 cfs provides ≈ 15 acres), followed by Dolly Varden (120 cfs provides ≈ 9.4 acres) and arctic grayling (410 cfs provides ≈ 9.2 acres) (Table 41; Figure 54). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 260 cfs for arctic grayling, 30 cfs or less for Dolly Varden, and 110 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and rainbow trout in SFK-A are generally similar, gradually increasing with flow until reaching a maximum and then remaining at a relatively high level over the remaining range of modeled flows. The relationship for Dolly Varden can be characterized as initially high at low flows but also remaining at a relatively high level over the remaining range of modeled flows.

4.2.1.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for SFK-A, as determined under an average water year type, are presented for all species on Figure 55 (spawning habitat) and Figure 56 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 57. In addition, Table 42 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.2.2 Reach SFK-B

Modeling results for SFK-B are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.2.2.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for SFK-B indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (120 cfs provides ≈ 14 acres), followed by sockeye salmon (160 cfs provides ≈ 11 acres), Chinook salmon (200 cfs provides ≈ 7.8 acres), and then coho salmon (160 cfs provides ≈ 5.5 acres) (Table 43; Figure 58). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 160 cfs for Chinook salmon, 100 cfs for chum salmon, 130 cfs for coho salmon, and 100 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in SFK-B are generally similar in shape. The habitat area increases at a moderate rate with increasing flow and, after reaching a maximum, gradually decreases. However, this shape occurs at progressively lower flows for Chinook, coho, sockeye, and chum salmon.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for SFK-B peak at flows of 150 cfs (provides ≈ 13 acres), 110 cfs , (provides ≈ 14 acres) and 120 cfs (provides ≈ 11 acres), respectively (Table 44; Figure 58). However, flows as low as 100 cfs for arctic grayling and 90 cfs for Dolly Varden and rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for SFK-B indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for Chinook salmon (120 cfs provides ≈ 6.2 acres), followed by coho salmon (380 cfs provides ≈ 4.2 acres) and sockeye salmon (400 cfs provides ≈ 4.1 acres) (Table 43; Figure 59). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 90 cfs for Chinook salmon, 240 cfs for coho salmon, and 220 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for coho and sockeye salmon in SFK-B are generally similar, exhibiting a decrease in habitat area at moderate flows. In contrast, habitat area for Chinook salmon is moderate at low flows, increases to a maximum as flows increase, and decreases to a moderate level at higher flows.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for SFK-Bat the habitat maximizing flow would be highest for arctic grayling (35 cfs provides ≈ 8.5 acres), followed by rainbow trout (140 cfs provides ≈ 5.7 acres), and then Dolly Varden (90 cfs provides ≈ 5.1 acres) (Table 44; Figure 59). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 30 cfs or less for arctic grayling, 40 cfs for Dolly Varden, and 90 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and Dolly Varden in SFK-B are generally similar, with habitat area initially high at low flows and remaining at moderate to high levels as flows increase. In contrast, habitat area for rainbow trout is initially moderate at low flows, increases to a maximum as flows increase, and remains at a relatively high level as flows continue to increase.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for SFK-B indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (110 cfs provides ≈ 9.3 acres), followed by Dolly Varden (400 cfs provides ≈ 5.8 acres) and then arctic grayling (160 cfs provides ≈ 4.4 acres) (Table 44; Figure 60). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 110 cfs for arctic grayling, 45 cfs for Dolly Varden, and 80 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and rainbow trout in SFK-B are generally similar, increasing with flow until reaching a maximum and then gradually decreasing over the remaining range of modeled flows. The relationship for Dolly Varden can be characterized as initially high at low flows, decreasing at moderate flows, and then increasing again over the remaining range of modeled flows.

4.2.2.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for SFK-B, as determined under an average water year type, are presented for all species on Figure 61 (spawning habitat) and Figure 62 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 63. In addition, Table 45 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.2.3 Reach SFK-C

Modeling results for SFK-C are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with SFK-C, except rainbow trout (Table 2). However, because rainbow trout have been observed in reaches upstream and downstream of SFK-C, this species may also inhabit SFK-C. Therefore, modeling results are presented for all species.

4.2.3.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for SFK-C indicate that the amount of habitat provided at the habitat maximizing flow would be highest for sockeye salmon (72 cfs provides ≈ 12 acres), followed by chum salmon (39 cfs provides ≈ 11 acres), coho salmon (64 cfs provides ≈ 7.4 acres), and Chinook salmon (72 cfs provides ≈ 5.0 acres) (Table 46; Figure 64). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 56 cfs for Chinook salmon, 30 cfs for chum salmon, 45 cfs for coho salmon, and 36 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in SFK-C are generally similar in shape. The habitat area increases at a moderate rate with increasing flow and, after reaching a maximum, gradually decreases. However, this shape occurs at progressively lower flows for Chinook, coho, sockeye, and chum salmon.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for SFK-C peak at flows of 72 cfs (provides ≈ 17 acres), 42 cfs (provides ≈ 13 acres), and 39 cfs (provides ≈ 7.8 acres), respectively (Table 47; Figure 64). However, flows as low as 48 cfs for arctic grayling, and 30 cfs for Dolly Varden and for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for SFK-C indicate that the amount of anadromous salmonid juvenile rearing habitat provided at the habitat maximizing flow would be highest for sockeye salmon (18 cfs provides ≈ 8.9 acres), followed by Chinook salmon (42 cfs provides ≈ 8.2 acres) and coho salmon (18 cfs provides ≈ 8.0 acres) (Table 46; Figure 65). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 24 cfs for Chinook salmon and 7 cfs for coho and sockeye salmon. When habitats are expressed as a percent of maximum, the relationships for coho and sockeye salmon in SFK-C are generally similar, with habitat area increasing to a maximum at relatively low flows and then decreasing at higher flows. The relationship for Chinook salmon is also similar, although the maximum habitat area is reached at higher flows.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for SFK-C at the habitat maximizing flow would be highest for arctic grayling (13 cfs provides ≈ 14 acres), followed by Dolly Varden (21 cfs provides ≈ 9.9 acres), and then rainbow trout (90 cfs provides ≈ 5.9 acres) (Table 47; Figure 65). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 5 cfs for arctic grayling, 7 cfs for Dolly Varden, and 48 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and Dolly Varden in SFK-C are generally similar, with habitat area increasing to a maximum at low flows and then decreasing as flows continue to

increase. In contrast, habitat area for rainbow trout generally increases asymptotically as flows increase over the modeled range.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for SFK-C indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (64 cfs provides ≈ 10 acres), followed by Dolly Varden (16 cfs provides ≈ 9.9 acres) and then arctic grayling (100 cfs provides ≈ 5.4 acres) (Table 47; Figure 66). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 72 cfs for arctic grayling, 7 cfs for Dolly Varden, and 42 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and rainbow trout in SFK-C are generally similar, gradually increasing with flow until reaching a maximum and then remaining at a moderate to high level over the remaining range of modeled flows. In contrast, the relationship for Dolly Varden can be characterized as initially increasing rapidly to a maximum at low flows and then gradually decreasing to a low to moderate level over the remaining range of modeled flows.

4.2.3.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for SFK-C, as determined under an average water year type, are presented for all species on Figure 67 (spawning habitat) and Figure 68 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 69. In addition, Table 48 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.2.4 Tributary SFK 1.190

Modeling results for Tributary SFK 1.190 are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. Only Chinook salmon, coho salmon, arctic grayling, Dolly Varden, and rainbow trout were observed in SFK 1.190 (Appendix 15.1B). However, because all of the above species have been documented (Table 2) in SFK-B (the reach into which SFK 1.190 flows) they are likely to inhabit SFK 1.190. Therefore, modeling results for all species are presented

4.2.4.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for SFK 1.190 indicate that the amount of habitat provided at the habitat maximizing flow would be highest for sockeye salmon (80 cfs provides ≈ 7.7 acres), followed by chum salmon (60 cfs provides ≈ 7.5 acres), coho salmon (110 cfs provides ≈ 5.9 acres), and Chinook salmon (95 cfs provides ≈ 3.6 acres) (Table 49; Figure 70). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 70 cfs for Chinook salmon, 39 cfs for chum salmon, 80 cfs for coho salmon, and 50 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in SFK 1.190 are generally similar in shape. The habitat area increases at a moderate rate with increasing flow and, after reaching a maximum, decreases more gradually. However, this shape occurs at progressively lower flows for coho, Chinook, sockeye, and chum salmon.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for SFK 1.190 peak at flows of 70 cfs (provides ≈ 8.5 acres), 45 cfs, (provides ≈ 8.1 acres) and 50 cfs (provides ≈ 7.1 acres), respectively (Table 50; Figure 70). However, flows as low as 50 cfs for arctic grayling, 30 cfs for Dolly Varden, and 39 cfs for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for SFK 1.190 indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for Chinook salmon (80 cfs provides ≈ 2.9 acres), followed by coho salmon (50 cfs provides ≈ 1.7 acres) and sockeye salmon (25 cfs provides ≈ 1.7 acres) (Table 49; Figure 71). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 60 cfs for Chinook salmon, 25 cfs for coho salmon, and 15 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the ascending limb for each species in SFK 1.190 is generally similar, with habitat area increasing to a maximum at flows between 25 and 80 cfs. However, habitat area for sockeye salmon rapidly decreases as flows increase further; whereas, habitat for Chinook salmon decreases more gradually and habitat for coho salmon remains at a high level.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for SFK 1.190 at the habitat maximizing flow would be highest for arctic grayling (20 cfs provides ≈ 4.6 acres), followed by Dolly Varden (30 cfs provides ≈ 2.7 acres) and rainbow trout (240 cfs provides ≈ 2.7 acres) (Table 50; Figure 71). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 13 cfs for arctic grayling, 20 cfs for Dolly Varden, and 90 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and rainbow trout in SFK 1.190 are generally similar, with habitat area gradually increasing to a maximum and then gradually decreasing to a moderate level at higher flows. In contrast, habitat area for rainbow trout increases rapidly at low flows and then continues to increase gradually as flows increase over the modeled range.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for SFK 1.190 indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (95 cfs provides ≈ 3.3 acres), followed by Dolly Varden (240 cfs provides ≈ 3.0 acres) and then arctic grayling (130 cfs provides ≈ 1.8 acres) (Table 50; Figure 72). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 100 cfs for arctic grayling, 160 cfs for Dolly Varden, and 70 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and rainbow trout in SFK 1.190 are generally similar, gradually increasing with flow until reaching a maximum and then remaining at a relatively high level over the remaining range of modeled flows. The relationship for Dolly Varden can be characterized as rapidly increasing at low flows and then gradually increasing over remaining range of modeled flows to reach a maximum at the highest modeled flow.

4.2.4.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for Tributary SFK 1.190, as determined under an average water year type, are presented for all species on Figure 73 (spawning habitat) and Figure 74 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on

Figure 75. In addition, Table 51 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.3 Upper Talarik Creek

4.3.1 Reach UT-B

Modeling results for UT-B are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.3.1.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for UT-B indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (90 cfs provides ≈ 19 acres), followed by Chinook salmon (135 cfs provides ≈ 12 acres), sockeye salmon (150 cfs provides ≈ 11 acres), and coho salmon (150 cfs provides ≈ 8.5 acres) (Table 52; Figure 76). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 120 cfs for Chinook salmon, 80 cfs or less for chum salmon, 120 cfs for coho salmon, and 105 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the habitat-flow relationships for anadromous salmonids in UT-B are generally similar in shape, where habitat area increases rapidly at low flows and, after reaching a maximum, decreases continually over the remaining range of modeled flows. The habitat-flow relationship for chum salmon is slightly different than other anadromous salmonids in that the habitat area is maximized at approximately the lowest modeled flow.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for UT-B peak at flows of 180 cfs, (provides ≈ 10 acres) 105 cfs (provides ≈ 14 acres), and 120 cfs (provides ≈ 7.7 acres), respectively (Table 53; Figure 76). However, flows as low as 135 cfs for arctic grayling, 80 cfs or less for Dolly Varden, and 90 cfs for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for UT-B indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for Chinook salmon (80 cfs provides ≈ 4.4 acres), followed by coho salmon (90 cfs provides ≈ 1.7 acres), and then sockeye salmon (80 cfs provides ≈ 1.1 acres) (Table 52; Figure 77). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 80 cfs or less for Chinook, coho, and sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in UT-B are similar in shape, generally decreasing from a maximum as flows increase.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for UT-B at the habitat maximizing flow would be highest for rainbow trout (80 cfs provides ≈ 4.2 acres), followed by arctic grayling (80 cfs provides ≈ 3.9 acres), and then Dolly Varden (80 cfs provides ≈ 1.9 acres) (Table 53;

Figure 77). For all three species, the lowest modeled flow provides the maximum amount of habitat and, in general, habitat area decreases as flows increase over the remaining range of modeled flows.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for UT-B indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (80 cfs provides ≈ 11 acres), followed by arctic grayling (135 cfs provides ≈ 4.8 acres), and then Dolly Varden (80 cfs provides ≈ 1.8 acres) (Table 53; Figure 78). When habitats are expressed as a percentage of maximum, the relationships for Dolly Varden and rainbow trout in UT-B are generally similar. The habitat amounts rapidly decreasing from a maximum as flows increase to around 100 to 200 cfs, and then remaining at a low to moderate level over the remaining range of modeled flows. The relationship for arctic grayling exhibits a similar pattern, although habitat amounts initially increase as flows increase from 80 to 135 cfs.

4.3.1.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for UT-B, as determined under an average water year type, are presented for all species on Figure 79 (spawning habitat) and Figure 80 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 81. In addition, Table 54 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.3.2 Reach UT-C

Modeling results for UT-C are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.3.2.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for UT-C indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (140 cfs provides ≈ 12 acres), followed by sockeye salmon (190 cfs provides ≈ 8.1 acres), coho salmon (180 cfs provides ≈ 6.6 acres), and Chinook salmon (180 cfs provides ≈ 4.5 acres) (Table 55; Figure 82). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 160 cfs for Chinook salmon, 70 cfs or less for chum salmon, and 130 cfs for coho and sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in UT-C are generally similar in shape. The habitat area increases rapidly at low flows and, after reaching a maximum, decreases continually over the remaining range of modeled flows. The relationship for chum salmon is slightly different in that habitat area is maximized closer to the lowest modeled flow.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for UT-C peak at flows of 190 cfs (provides ≈ 8.0 acres), 150 cfs (provides ≈ 10 acres), and 140 cfs (provides ≈ 6.6

acres), respectively (Table 56; Figure 82). However, flows as low as 160 cfs for arctic grayling and 100 cfs for Dolly Varden and rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for UT-C indicate that the amount of anadromous salmonid juvenile rearing habitat provided at the habitat maximizing flow would be highest for coho salmon (680 cfs provides ≈ 5.3 acres), followed by sockeye salmon (680 cfs provides ≈ 5.0 acres), and then Chinook salmon (680 cfs provides ≈ 4.2 acres) (Table 55; Figure 83). Although the highest modeled flow (680 cfs) would provide the greatest amount of habitat for all three species, the habitat area provided at the lowest modeled flow (70 cfs) would still provide from 65% (for sockeye salmon) to 97% (for Chinook salmon) of the maximum habitat area. In general, moderate flows within the modeled range would provide lesser amounts of habitat. When habitats are expressed as percentage of maximum, the relationships for anadromous salmonids in UT-C are generally similar in shape. The habitat is initially high at low flows, decreases over moderate flows, and then increases again approaching the highest modeled flow.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for UT-C at the habitat maximizing flow would be highest for arctic grayling (680 cfs provides ≈ 11 acres), followed by Dolly Varden (680 cfs provides ≈ 6.2 acres), and then rainbow trout (90 cfs provides ≈ 3.6 acres) (Table 56; Figure 83). Relationships for these species exhibit a trend similar to that for anadromous salmonids, in which habitat area is initially high at low flows, decreases over moderate flows, and then increases again approaching the highest modeled flow.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for UT-C indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (80 cfs provides ≈ 6.7 acres), followed by Dolly Varden (680 cfs provides ≈ 6.1 acres), and then arctic grayling (160 cfs provides ≈ 2.8 acres) (Table 56; Figure 84). When habitats are expressed as a percentage of maximum, the relationships for all three species in UT-C exhibit a generally similar trend in which habitat amounts are relatively high at low flows and decrease to moderate levels as flows increase. One exception is at flows greater than 240 cfs Dolly Varden habitat increases over the remaining range of modeled flows.

4.3.2.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for UT-C, as determined under an average water year type, are presented for all species on Figure 85 (spawning habitat) and Figure 86 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 87. In addition, Table 57 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.3.3 Reach UT-D

Modeling results for UT-D are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.3.3.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for UT-D indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (110 cfs provides ≈ 19 acres), followed by sockeye salmon (130 cfs provides ≈ 16 acres), coho salmon (140 cfs provides ≈ 13 acres), and Chinook salmon (170 cfs provides ≈ 7.6 acres) (Table 58; Figure 88). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 130 cfs for Chinook salmon, 80 cfs for chum salmon, 110 cfs for coho salmon, and 100 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in UT-D are generally similar in shape. The habitat area increases at a moderate rate with increasing flow and, after reaching a maximum, decreases at a moderate rate. However, this shape is shifted towards progressively lower flows for Chinook, coho, sockeye, and chum salmon.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for UT-D peak at flows of 150 cfs (provides ≈ 19 acres), 120 cfs (provides ≈ 20 acres), and 90 cfs (provides ≈ 14 acres), respectively (Table 59; Figure 88). However, flows as low as 100 cfs for arctic grayling, 80 cfs for Dolly Varden, and 65 cfs for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for UT-D indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for Chinook salmon (110 cfs provides ≈ 4.2 acres), followed by coho salmon (40 cfs provides ≈ 3.4 acres), and then sockeye salmon (40 cfs provides ≈ 2.2 acres) (Table 58; Figure 89). For both coho and sockeye salmon, habitat is maximized at the lowest modeled flow (40 cfs) and initially decreases at a rapid rate as flows increase before leveling. In contrast, habitat for Chinook salmon is initially high (greater than 90% of maximum) at low flows (40 to 110 cfs) and then gradually decreases as flows increase.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for UT-D at the habitat maximizing flow would be highest for arctic grayling (40 cfs provides ≈ 6.4 acres), followed by rainbow trout (140 cfs provides ≈ 4.7 acres), and then Dolly Varden (40 cfs provides ≈ 4.3 acres) (Table 59; Figure 89). Habitat amounts remain relatively high (≈ 90% of maximum) at flows between 100 and 200 cfs for rainbow trout. However, habitat for arctic grayling and Dolly Varden in UT-D is maximized at the lowest modeled flow (40 cfs), and generally decreases at a relatively rapid rate as flows increase.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for UT-D indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (65 cfs provides ≈ 8.4 acres), followed by Dolly Varden (40 cfs provides ≈ 4.4 acres) and then arctic grayling (150 cfs provides ≈ 4.3 acres) (Table 59; Figure 90). When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and rainbow trout in UT-D are generally similar in shape. The habitat area increases with flow until reaching a maximum, and then gradually decreases over the remaining range of modeled flows. However, the curve for arctic grayling is shifted

towards higher flows. In contrast, the habitat area for Dolly Varden is maximized at the lowest modeled flow and decreases asymptotically over the remaining range of modeled flows.

4.3.3.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for UT-D, as determined under an average water year type, are presented for all species on Figure 91 (spawning habitat) and Figure 92 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 93. In addition, Table 60 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.3.4 Reach UT-E

Modeling results for UT-E are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.3.4.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for UT-E indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (120 cfs provides ≈ 13 acres), followed by coho salmon (160 cfs provides ≈ 12 acres), sockeye salmon (150 cfs provides ≈ 11 acres), and Chinook salmon (260 cfs provides ≈ 5.7 acres) (Table 61; Figure 94). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 200 cfs for Chinook salmon, 80 cfs for chum salmon, 110 cfs for coho salmon, and 90 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in UT-E are generally similar in shape. The habitat area rapidly increases with increasing flow and, after reaching a maximum, gradually decreases to a moderate level. However, this shape is shifted towards lower flows for chum and sockeye salmon and towards higher flows for coho salmon and, in particular, Chinook salmon.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for UT-E peak at flows of 150 cfs (provides ≈ 17 acres), 120 cfs (provides ≈ 16 acres), and 90 cfs (provides ≈ 12 acres), respectively (Table 62; Figure 94). However, flows as low as 90 cfs for arctic grayling and 70 cfs for Dolly Varden and rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for UT-E indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for coho salmon (550 cfs provides ≈ 6.1 acres), followed by Chinook salmon (170 cfs provides ≈ 5.9 acres) and sockeye salmon (550 cfs provides ≈ 5.8 acres) (Table 61; Figure 95). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 100 cfs for Chinook salmon and 90 cfs for coho salmon. However, for sockeye salmon, habitat is maximized at the highest modeled flow (550 cfs) and is generally less than 70% of maximum at flows less than 430 cfs.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for UT-E at the habitat maximizing flow would be highest for arctic grayling (550 cfs provides ≈ 12 acres), followed by Dolly Varden (550 cfs provides ≈ 6.6 acres), and rainbow trout (320 cfs provides ≈ 6.5 acres) (Table 62; Figure 95). Habitat amount remain relatively high (≈ 90% of maximum) at flows from 180 to 550 cfs for rainbow trout. However, for arctic grayling and Dolly Varden in UT-E, habitat is maximized at the highest modeled flow (550 cfs) is less than 90% of maximum at flows less than 510 cfs.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for UT-E indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (200 cfs provides ≈ 8.2 acres), followed by Dolly Varden (550 cfs provides ≈ 7.0 acres), and then arctic grayling (320 cfs provides ≈ 5.5 acres) (Table 62; Figure 96). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 240 cfs for arctic grayling and 150 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and rainbow trout in UT-E are generally similar. The habitat area increases with flow until reaching a maximum and then gradually decreases to a moderate level over the remaining range of modeled flows. The relationship for Dolly Varden can be characterized as rapidly increasing to an initial peak at 100 cfs (≈ 85% of maximum), decreasing at moderate flows (up to around 350 cfs), and then continuing to increase over the remaining range of modeled flows to reach a maximum at the highest modeled flow (550 cfs).

4.3.4.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for UT-E, as determined under an average water year type, are presented for all species on Figure 97 (spawning habitat) and Figure 98 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 99. In addition, Table 63 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.3.5 Reach UT-F

Modeling results for UT-F are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.3.5.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for UT-F indicate that the amount of habitat provided at the habitat maximizing flow would be highest for chum salmon (20 cfs provides ≈ 5.1 acres), followed by coho salmon (45 cfs provides ≈ 5.0 acres), sockeye salmon (42 cfs provides ≈ 4.9 acres), and Chinook salmon (60 cfs provides ≈ 1.4 acres) (Table 64; Figure 100). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 45 cfs for Chinook salmon, 16 cfs for chum salmon, 24 cfs for coho salmon, and 20 cfs for sockeye salmon. When habitats are expressed as percentage of maximum, the relationships for chum, coho, and sockeye salmon in UT-F are generally

similar in shape. The habitat area increases at a moderate rate with increasing flow and remains at a relatively high level as flows continue to increase. In contrast, habitat area for Chinook salmon increases more slowly with increasing flows.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for UT-F peak at flows of 32 cfs (provides ≈ 8.4 acres), 22 cfs (provides ≈ 7.9 acres), and 24 cfs (provides ≈ 5.3 acres), respectively (Table 65; Figure 100). However, flows as low as 22 cfs for arctic grayling and 16 cfs for Dolly Varden and rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for UT-F indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for coho salmon (8 cfs provides ≈ 4.0 acres), followed by sockeye salmon (8 cfs provides ≈ 2.8 acres) and Chinook salmon (8 cfs provides ≈ 2.4 acres) (Table 64; Figure 101). At flows greater than 8 cfs, the habitat area for coho and sockeye salmon would gradually decrease, whereas the habitat area for Chinook salmon would be high (> 90% of maximum) as flows increase over the remaining range of modeled flows.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for UT-F at the habitat maximizing flow would be highest for arctic grayling (8 cfs provides ≈ 6.0 acres), followed by Dolly Varden (8 cfs provides ≈ 4.0 acres), and rainbow trout (54 cfs provides ≈ 2.3 acres) (Table 65; Figure 101). For both arctic grayling and rainbow trout, habitat amounts rapidly increase as flows approach 8 cfs and then gradually decrease over the remaining range of modeled flows. In contrast, habit amounts for rainbow trout increase as flows increase and then remain relatively high (≈ 90% of maximum) at flows of 16 cfs or more.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for UT-F indicate that the amount of habitat provided at the habitat maximizing flow would be highest for Dolly Varden (10 cfs provides ≈ 4.8 acres), followed by rainbow trout (24 cfs provides ≈ 4.2 acres), and then arctic grayling (60 cfs provides ≈ 1.9 acres) (Table 65; Figure 102). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 45 cfs for arctic grayling, 7 cfs for Dolly Varden, and 16 cfs for rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and rainbow trout in UT-F are generally similar, gradually increasing with flow until reaching a maximum and then remaining at a relatively high level over the remaining range of modeled flows. The relationship for Dolly Varden can be characterized as rapidly increasing to a maximum at low flows (10 cfs), and then gradually decreasing over remaining range of modeled flows.

4.3.5.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for UT-F, as determined under an average water year type, are presented for all species on Figure 103 (spawning habitat) and Figure 104 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 105. In addition, Table 66 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.3.6 Tributary UT 1.190

Modeling results for Tributary UT 1.190 are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. While it is unclear whether all of these species inhabit UT 1.190, they have all been documented in UT-C, the reach into which UT 1.190 flows (Table 2). Therefore, modeling results are presented for all species.

4.3.6.1 PHABSIM Analysis

Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for UT 1.190 indicate that the amount of habitat provided at the habitat maximizing flow would be highest for sockeye salmon (24 cfs provides ≈ 1.1 acres), followed by chum salmon (18 cfs provides ≈ 0.6 acres), coho salmon (24 cfs provides ≈ 0.3 acres), and Chinook salmon (24 cfs provides less than 1 acre) (Table 67; Figure 106). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 21 cfs for Chinook salmon, 12 cfs for chum salmon, 21 cfs for coho salmon, and 18 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in UT 1.190 are generally similar in shape, where habitat area increases rapidly with increasing flow and, after reaching a maximum, gradually decreases over the remaining range of modeled flows. However, for Chinook and coho salmon, habitat area remains at a somewhat higher level and fluctuates compared to chum and sockeye salmon as flows increase.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for UT 1.190 peak at flows of 39 cfs (provides ≈ 0.6 acres), 24 cfs (provides ≈ 1.2 acres), and 18 cfs (provides ≈ 1.1 acres), respectively (Table 68; Figure 106). However, flows as low as 24 cfs for arctic grayling, 18 cfs for Dolly Varden, and 12 cfs for rainbow trout would still provide ≈ 90% of maximum spawning habitat.

Juvenile Rearing Habitat

Habitat-flow relationships generated for UT-1.190 indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for sockeye salmon (120 cfs provides ≈ 0.4 acres), followed by coho salmon (120 cfs provides ≈ 0.3 acres) and Chinook salmon (120 cfs provides ≈ 0.2 acres) (Table 67; Figure 107). Habitat amounts for all three species generally increase at a relatively constant rate before reaching a maximum at the highest modeled flow (120 cfs).

For non-anadromous salmonids, the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for arctic grayling (120 cfs provides ≈ 0.6 acres), followed by Dolly Varden (120 cfs provides ≈ 0.3 acres), and then rainbow trout (120 cfs provides ≈ 0.1 acres) (Table 68; Figure 107). Like the anadromous salmonid species, habitat amounts for these three species generally increase at a relatively constant rate before reaching a maximum at the highest modeled flow (120 cfs). However, over the range of flows from 12 to 24 cfs, habitat amounts for arctic grayling initially decrease before following a trend similar to the other species and increasing as flows increase.

Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for UT-1.190 indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (12 cfs provides ≈ 0.25 acres) and Dolly Varden (120 cfs provides ≈ 0.3 acres), followed by arctic grayling (120 cfs provides ≈ 0.03 acres) (Table 68; Figure 108). When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and Dolly Varden in UT 1.190 are similar, generally increasing gradually with flow until reaching a maximum at the highest modeled flow. In contrast, the habitat area for rainbow trout decreases rapidly from a maximum at the lowest modeled flow (12 cfs) and then remains at a low level over the remaining range of modeled flows.

4.3.6.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for Tributary UT-1.190, as determined under an average water year type, are presented or all species on Figure 109 (spawning habitat) and Figure 110 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 111. In addition, Table 69 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

4.4 Mainstem Koktuli River

Modeling results for the KR are presented for: Chinook, chum, coho, and sockeye salmon; arctic grayling; Dolly Varden; and rainbow trout. All of these species have been documented in habitat associated with this reach (Table 2).

4.4.1 PHABSIM Analysis

4.4.1.1 Spawning Habitat

For anadromous salmonid species, spawning habitat - flow relationships generated for the KR indicate that the amount of habitat provided at the habitat maximizing flow would be highest for sockeye salmon (200 cfs provides ≈ 58 acres), followed by chum salmon (160 cfs provides ≈ 50 acres) and coho salmon (510 cfs provides ≈ 50 acres), and then Chinook salmon (510 cfs provides ≈ 18 acres) (Table 70; Figure 112). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 370 cfs for Chinook salmon, ≤ 140 cfs for chum salmon, 260 cfs for coho salmon, and 140 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids are generally similar in shape. The habitat area increases rapidly with increasing flow and, after reaching a maximum, gradually decreases over the remaining range of modeled flows. However, for chum and sockeye salmon, habitat area is maximized at considerably lower flows than for Chinook and coho salmon.

The habitat-flow relationships for spawning arctic grayling, Dolly Varden, and rainbow trout for KR peak at flows of 340 cfs (provides ≈ 83 acres), 200 cfs (provides ≈ 82 acres), and 160 cfs (provides ≈ 62 acres), respectively (Table 71; Figure 112). However, flows as low as 200 cfs for arctic grayling, and 140 cfs or less for Dolly Varden and rainbow trout would still provide ≈ 90% of maximum spawning habitat.

4.4.1.2 Juvenile Rearing Habitat

Habitat-flow relationships generated for the KR indicate that the amount of juvenile rearing habitat provided at the habitat maximizing flow would be highest for Chinook salmon (480 cfs provides ≈ 24 acres), followed by coho salmon (1,100 cfs provides ≈ 20 acres) and sockeye salmon (1,100 cfs provides ≈ 20 acres) (Table 70; Figure 113). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 370 cfs for Chinook salmon, 370 cfs for coho salmon, and 340 cfs for sockeye salmon. When habitats are expressed as a percentage of maximum, the relationships for anadromous salmonids in the KR are generally similar in shape. The habitat area increases rapidly as flows increase to around 340 cfs and then remains at a relatively high level over the remaining range of modeled flows.

For non-anadromous salmonids, the amount of juvenile rearing habitat provided for the KR at the habitat maximizing flow would be highest for arctic grayling (430 cfs provides ≈ 32 acres), followed by Dolly Varden (430 cfs provides ≈ 23 acres), and rainbow trout (510 cfs provides ≈ 22 acres) (Table 71; Figure 113). Habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 340 cfs for arctic grayling and 370 cfs for Dolly Varden and rainbow trout. When habitats are expressed as a percentage of maximum, the relationships for non-anadromous salmonids are generally similar in shape. The habitat area increases as flows increase to around 400 cfs and then remains at a relatively high level over the remaining range of modeled flows.

4.4.1.3 Adult Rearing Habitat

For non-anadromous salmonid species, adult rearing habitat - flow relationships generated for the KR indicate that the amount of habitat provided at the habitat maximizing flow would be highest for rainbow trout (510 cfs provides ≈ 25 acres), followed by Dolly Varden (1,100 cfs provides ≈ 24 acres), and then arctic grayling (660 cfs provides ≈ 14 acres) (Table 71; Figure 114). When habitats are expressed as a percentage of maximum, the relationships for arctic grayling and Dolly Varden in the KR are generally similar, increasing with flow until reaching a maximum and then remaining at a relatively high level over the remaining range of modeled flows. In contrast, habitat area for rainbow trout remains at greater than 90% of maximum over the full range of modeled flows. For arctic grayling and Dolly Varden, habitat amounts remain relatively high (≈ 90% of maximum) at flows as low as 310 cfs and 400 cfs, respectively.

4.4.2 Habitat Time Series

Habitat time series and corresponding habitat duration curves for the KR, as determined under an average water year type, are presented for all species on Figure 115 (spawning habitat) and Figure 116 (juvenile rearing habitat). Results for non-anadromous salmonid adult rearing habitat are presented on Figure 117. In addition, Table 72 summarizes the average daily habitat area provided for all species and lifestages during wet, average, and dry water year types.

5. DISCUSSION

This study is one of several studies focused on understanding the current relationships and dynamics between streamflow and habitat form and function in the NFK, SFK, UT, and KR systems of the Pebble Project. This study resulted in the derivation of habitat (as indexed by WUA) – flow relationships for 117 transects established in selected reaches of these systems for various target fish species and lifestages.

These relationships (see Attachment 2) were subsequently used in developing time series and habitat duration analysis (see for example Figure 14) for each transect. These describe how habitats for a particular species and lifestage vary throughout the period of the salient lifestage (e.g., spawning periods vary by species and only occur for several months; rearing periods vary by species, etc.) under different water year types (wet, average, dry). A reach-specific habitat area versus flow relationship was computed for various reaches of each system via the weighting of transects in a reach based on habitat types and results of habitat mapping (see, for example, Figure 28). These were subsequently used for completing a habitat time series and habitat duration analysis on a reach basis under average flow conditions (see, for example, Figure 31). In addition, the average habitat area available on a daily basis in each reach was summarized and presented in tabular format for each water year type by species and lifestage (see, for example, Table 30).

These analytical results can be used in a variety of ways in helping to understand the baseline conditions in the Pebble Project area and specifically how, when, and where the existing hydrology of the Pebble Project area influences the amounts of habitat of the target fish species. The range of analyses can extend from an extremely localized assessment using the individual transect habitat-flow relationships (Attachment 2), to a broader reach-scale assessment provided in the habitat area summary tables by reach (e.g., Table 30). For example, Figure 1 in Attachment 2, Supplement 1 is for an individual transect (Transect 05-NFK1-IC3) and clearly shows a pattern of increasing spawning habitat as flow increases up to a peak (representing the flow that provides the greatest amount of habitat) and then habitat begins to decrease as flows continue to increase. The figures on the left side represent habitat amounts, while those on the right represent normalized values. The figures allow for spatial comparisons of habitat-versus-flow relationships both within and between streams.

On a broader scale, the habitat area by reach results tables (e.g., Table 30) indicate that, in general, the amounts of spawning habitat area are more sensitive to water year types than rearing habitats; i.e., more habitat is provided during wet years than is available during dry years. For example, Table 30 shows that spawning habitat areas (see Chinook, coho, and sockeye salmon) are highest under wet year conditions, and the areas progressively decrease under average and low flow water year conditions. In contrast, the amount of rearing habitat tends to remain relatively constant over all water year types.

Non-anadromous salmonid rearing habitat amounts likewise follow this same trend of being relatively insensitive to water year types. However, the patterns of spawning habitat for grayling and rainbow trout (in NFK-A) differ from the anadromous salmonids in that the maximum amount of habitat would be provided under dry water year conditions rather than wet. This is likely a result of differences in the HSC criteria, with both of these species having lower velocities associated with spawning habitats.

The above patterns occur for many, but not all of the other reaches. For example, the pattern of spawning habitat for anadromous salmonid spawning in UT-B (Table 54) shows the exact opposite trend, i.e., spawning habitat area is highest under dry year conditions and lowest under wet year conditions. These types of differences may reflect difference in channel- and reach-specific hydrologic characteristics.

Table 73 extends the analysis even further and provides a comparative summary of habitat area estimated in each stream (for reaches containing transect information) under average flow conditions by species and lifestage. The table indicates that the amounts of habitat area by species and lifestage provided under average flow conditions vary by stream system. In general, the greatest amount of Chinook and sockeye salmon spawning habitats are found in the SFK, while the UT and NFK contain the greatest amounts of

coho and chum salmon habitats, respectively. The NFK is estimated to contain more juvenile Chinook, coho, chum, and sockeye salmon rearing habitats than both the SFK and UT.

Overall, the analysis resulting from this study, in combination with the results from other flow-related studies (Appendix 15.1D, Appendix 15.1E, and Appendix 15.1F), provides a solid framework of information from which to characterize baseline habitat conditions in the NFK, SFK, UT, and KR systems.

7. GLOSSARY

Accretion—A gradual increase in flow within a river, resulting from tributary inputs or upwelling groundwater.

Adfluvial—Fish that spend a part of their life cycle in lakes and return to rivers and streams to spawn.

Anadromous—Fish that spend a part of their life cycle in the sea and return to freshwater streams to spawn.

Backwater—A small, generally shallow body of water attached to the main channel with little or no current of its own pushed back by a dam or current.

Bank—The sloping land bordering a stream channel that forms the usual boundaries of a channel. The bank has a steeper slope than the bottom of the channel and is usually steeper than the land surrounding the channel.

Base flow—The component of a flow regime that represents normal flow conditions sustained by groundwater between precipitation events.

Calibration—The validation of specific measurement techniques and equipment, or the comparison between measurements. In the context of PHABSIM, calibration is the process of adjusting input variables to minimize the error between predicted and observed water surface elevations.

Cascade—The steepest of riverine habitat types. Unlike rapids, which have an even gradient, cascades consist of a series of small steps of alternating small waterfalls and shallow pools.

Channel—A watercourse that continuously or intermittently contains water, with definite bed and banks that confine all but overbank streamflows.

Channel morphology—The planform, pattern, shape, and structure of a stream channel.

Confluence—The junction of two or more streams.

Cover—Protective shelter, objects within or immediately overhanging a stream that fish use to hide from predators.

Drainage area—An area of land upstream of a particular point where all runoff from rain or snow melt drains downhill to the same outlet such as a river, lake, reservoir, estuary, wetland, sea, or ocean. Also known as a catchment area, or drainage basin.

Fluvial—Of or pertaining to the processes associated with rivers and streams and the deposits and landforms created by them.

Glide—Section of stream that has a smooth water surface, laminar flow path, and generally greater depth, but no clear scour feature.

Gradient—The slope of the stream channel expressed as a percent of rise per unit length.

Habitat Suitability Curve (HSC) —A graph/mathematical equation describing the suitability for use by various species/lifestages of fish of areas within a stream channel related to water depth, velocity, and substrate.

Hyporheic Zone —The saturated area beneath the streambed that contains a combination of surface and groundwater flow.

Iteroparous—Fish species that can reproduce repeatedly during their lifetime.

Large Woody Debris (LWD)—Pieces of wood larger than 10 feet long and 6 inches in diameter, in a stream channel.

Mesohabitat—Basic structural elements of a river or stream such as pools, backwaters, runs, glides, and riffles.

PHABSIM (Physical Habitat Simulation)—PHABSIM is a set of computer programs that provides predictive relationships between flow changes and various physical and hydraulic characteristics that relate to the amounts of habitat of different fish species and lifestages. The results of a PHABSIM analysis are generally reported in terms of Weighted Useable Area (WUA) versus flow. PHABSIM represents the computer programs associated with the Instream Flow Incremental Methodology process.

Pool—Relatively deep area in a natural stream channel with low velocity and smooth water surface as compared to other portions of the stream.

Rearing—Rearing is the term used by fish biologists that considers the period of time in which juvenile fish feed and grow. In the case of anadromous fish, the end of the juvenile rearing period culminates when the fish undergo smoltification, a process that results in physiological changes to the fish that readies it for transitioning to saltwater.

Rearing habitat—Areas in rivers or streams where fry, juvenile, and adult fish find food and shelter to live and grow.

Redd—A depression in the stream bottom created by spawning activities of salmon or trout. Sometimes called an egg nest, a redd consists of an upper depression or pit in the substrate that is followed by a small mound of gravel within which are buried the fertilized ova of salmon or trout.

Riffle—Shallow rapids in an open stream where the water surface is broken into waves by obstructions wholly or partly submerged.

Riparian zone—Vegetation along the banks of a stream or river that is influenced by the presence of water flow within the stream, including surface flow and hyporheic flow.

Run—A section of stream characterized by deep, fast, low turbulence water.

Semelparous—Fish species that reproduce only once during their lifetime.

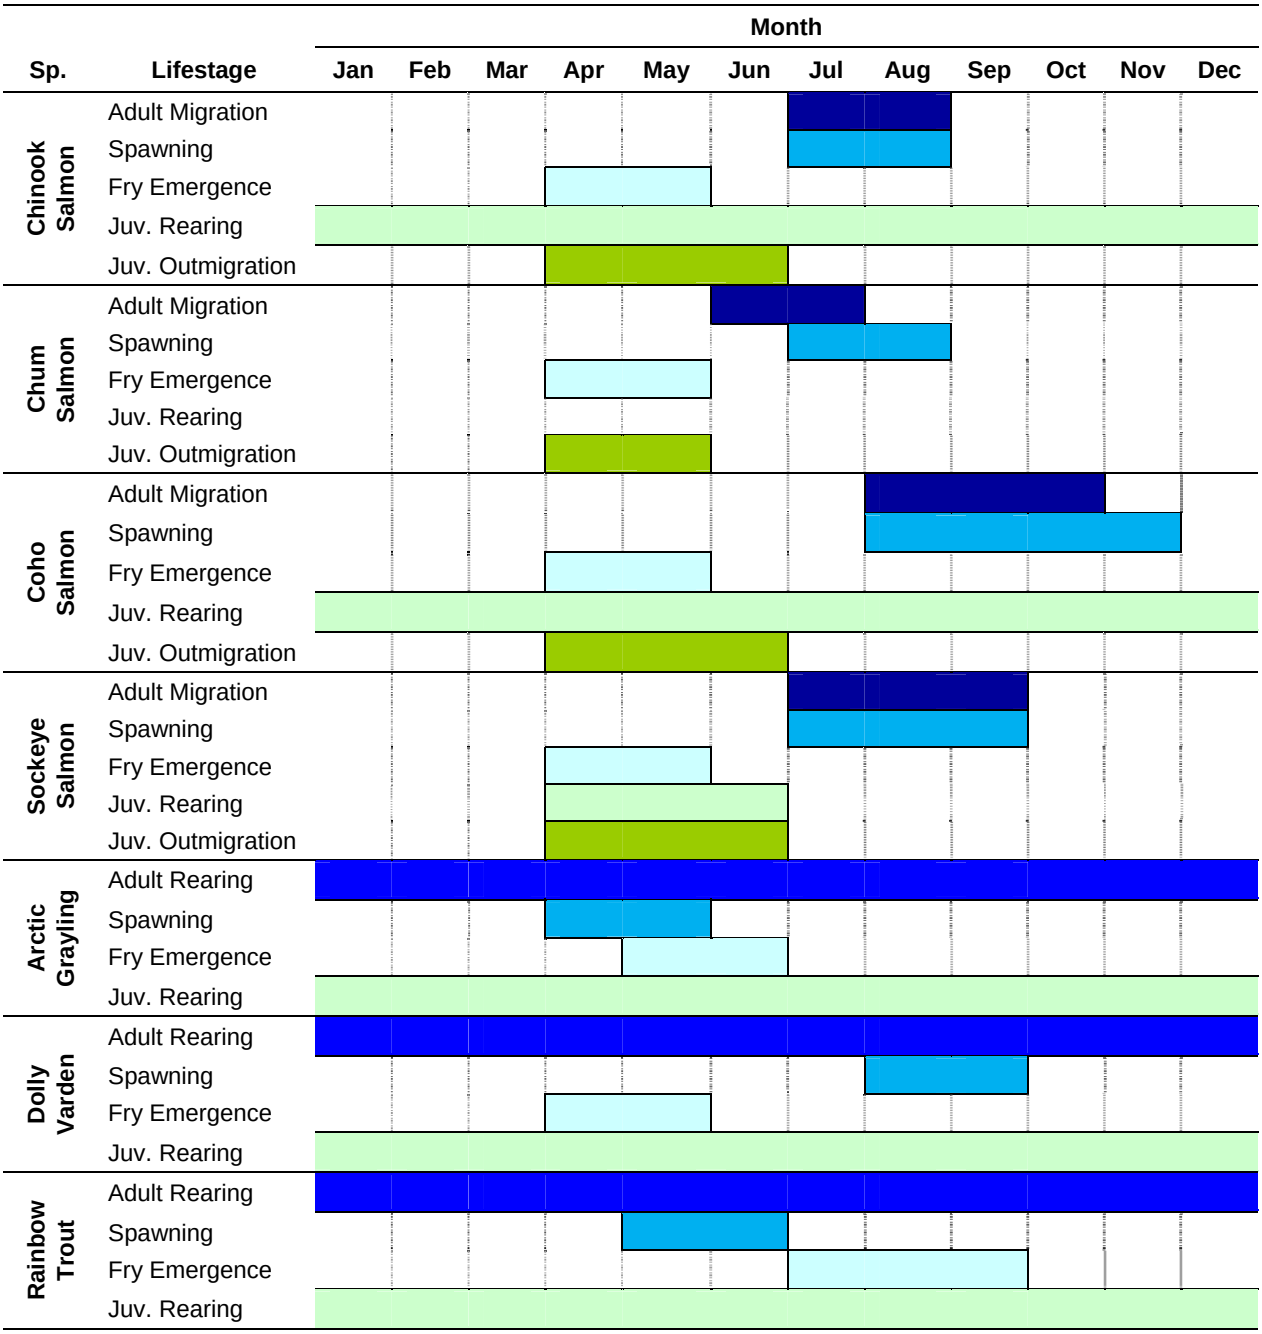
Substrate—The material composing the streambed, including either mineral or organic matter.

Transect—A predetermined line along which depth, velocity, or other characteristics such as substrate or cover are measured as partial input into the PHABSIM model.

Weighted Usable Area (WUA) —An index of fish habitat within a stream or river. WUA is weighted by its suitability as habitat, as defined by Habitat Suitability Criteria for different fish species and lifestages (see PHABSIM).

TABLES

TABLE 1
Life-history Stage Periodicity for Target Species in the Fish Resource Study Area



Note:

Based on general understanding of local populations (developed from R2 Resource Consultants, Inc., 2009) (Subject to revision). Note that information regarding adult rearing periodicity for non-anadromous salmonids is limited in the study area and was, therefore, assumed to extend throughout the year for the purposes of the instream flow analysis.

TABLE 2
Distribution of Target Species in the Study Area Based on Observations from 2004 to 2008

Note :

Bold text indicates reaches in which instream flow transects were established. Not bolded “X” indicates that species presence was documented in mainstem, tributary, or off-channel habitat assigned to the corresponding reach. Transects were also established in Tributaries NFK 1.190, SFK 1.190, and UT 1.190.

Source: Appendix 15.1B.

TABLE 3
Instream Flow Transects by Reach, Habitat Type, River Kilometer, and River Mile for 117 PHABSIM Transects Established in the Study Area, 2004 through 2008

Reach	Transect	Habitat Type	River Kilometer	River Mile
NFK-A	05-NFK1-IC3	Island Complex	3.37	2.09
NFK-A	08-NFK1-MS1-TR1	Island Complex	9.88	6.14
NFK-A	08-NFK1-MS1-TR2	Run	9.91	6.16

Notes:

a. Transect located in Tributary NFK 1.190.

b. Transect located in Tributary SFK 1.190.

c. Transect located in Tributary UT 1.190.

River Kilometer and River Mile in the NFK and SFK basins are measured from the confluence of the North and South Forks of the Koktuli River; River Kilometer and River Mile in the UT basin are measured from Iliamna Lake; River Kilometer and River Mile in the KR basin are measured from the Swan River; River Kilometer and River Mile of each tributary are measured from the mainstem river in each respective basin (i.e., NFK, SFK, and UT).

TABLE 4
Modified Wentworth Scale for Substrate Size Classification, Instream Flow Study

Description	Size Class (metric/English)	Code
Fines	< 2 mm/< 0.1 in.	FI
Small Gravel	2-16 mm/0.1-0.6 in.	SG
Large Gravel	16-64 mm/0.6-2.5 in.	LG
Small Cobble	64-128 mm/2.5-5.0 in.	SC
Large Cobble	128-256 mm/5.0-10.0 in.	LC
Boulder	> 256 mm/> 10.0 in.	BO
Bedrock	Bedrock	BR

Key:
> = greater than
< = less than
in. = inch(es)
mm = millimeter(s)

TABLE 5
Cover Codes, Instream Flow Study

Description	Code
Boulder	BO
Large Woody/Organic Debris	LWD
Instream Vegetation	IV
Overhanging Vegetation	OV
Undercut Bank	UCB

TABLE 6
Microhabitat Data Collected at Redd Locations in the NFK, SFK, and UT Watersheds, 2005, 2006, and 2008

	Percent of Total Redds Sampled for which Each Parameter Was Recorded		
Parameter	**2005**	**2006**	**2008**

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

TABLE 33
Average Daily Habitat Area for Target Species and Lifestages in NFK-B

		Avg. Daily Habitat Area (acres) by Water Year Type		
Species	**Lifestage**	**Wet**	**Average**	**Dry**
Chinook Salmon	Spawning	6.68	5.77	2.92
	Juvenile	8.4	7.96	7.00
Chum Salmon	Spawning	15.08	16.90	16.68
Coho Salmon	Spawning	8.25	8.59	8.82
	Juvenile	10.54	10.00	9.06
Sockeye Salmon	Spawning	7.96	8.40	8.73
	Juvenile	10.81	9.79	10.12
Arctic Grayling	Spawning	7.28	8.03	9.31
	Juvenile	16.37	16.07	15.19
	Adult	3.35	3.27	2.59
Dolly Varden	Spawning	10.93	11.22	13.10
	Juvenile	11.25	10.94	10.20
	Adult	10.93	10.43	9.76
Rainbow Trout	Spawning	3.60	4.94	6.23
	Juvenile	5.67	5.40	4.75
	Adult	8.14	8.05	7.16

Note:

Provided during wet, average, and dry water year types, as determined from habitat duration analysis for NFK-B, North Fork Koktuli River, Alaska.

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage. When two flows are indicated as providing 100 percent of habitat, the lower of the two flows was referenced in the text.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

TABLE 42
Average Daily Habitat Area for Target Species and Lifestages in SFK-A

Species	Lifestage	Avg. Daily Habitat Area (acres) by Water Year Type		
		Wet	Average	Dry
Chinook Salmon	Spawning	15.73	15.92	8.27
	Juvenile	8.25	7.63	7.20
Chum Salmon	Spawning	33.72	35.74	33.13
Coho Salmon	Spawning	16.80	16.22	15.23
	Juvenile	5.43	5.40	5.34
Sockeye Salmon	Spawning	24.72	23.63	24.42
	Juvenile	5.78	5.77	6.17
Arctic Grayling	Spawning	23.16	18.34	23.78
	Juvenile	15.28	15.27	15.50
	Adult	5.70	5.12	4.28
Dolly Varden	Spawning	35.10	32.43	35.79
	Juvenile	8.77	8.74	8.72
	Adult	8.75	8.65	8.52
Rainbow Trout	Spawning	19.67	20.59	24.05
	Juvenile	8.57	7.86	6.95
	Adult	12.99	12.32	11.58

Note:

Provided during wet, average, and dry water year types, as determined from habitat duration analysis for SFK-A, South Fork Koktuli River, Alaska.

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage. When two flows are indicated as providing 100 percent of habitat, the lower of the two flows was referenced in the text.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

TABLE 54
Average Daily Habitat Area for Target Species and Lifestages in UT-B

		Avg. Daily Habitat Area (acres) by Water Year Type		
Species	**Lifestage**	**Wet**	**Average**	**Dry**
Chinook Salmon	Spawning	5.03	6.33	8.96
	Juvenile	1.27	1.23	1.51
Chum Salmon	Spawning	4.75	5.57	7.73
Coho Salmon	Spawning	3.84	4.42	4.32
	Juvenile	0.89	0.89	1.02
Sockeye Salmon	Spawning	6.21	6.78	7.80
	Juvenile	0.45	0.50	0.58
Arctic Grayling	Spawning	6.99	7.20	7.60
	Juvenile	1.77	1.75	1.92
	Adult	2.11	2.19	2.74
Dolly Varden	Spawning	6.43	7.29	8.03
	Juvenile	0.90	0.91	0.99
	Adult	0.87	0.88	0.93
Rainbow Trout	Spawning	3.42	4.53	5.35
	Juvenile	2.45	2.49	2.89
	Adult	2.32	2.09	2.58

Note:

Provided during wet, average, and dry water year types, as determined from habitat duration analysis for UT-B, Upper Talarik Creek, Alaska.

680	73.2	100.0	69.3	62.0	100.0	100.0	41.9	92.1	54.9

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage. When two flows are indicated as providing 100 percent of habitat, the lower of the two flows was referenced in the text.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

TABLE 57
Average Daily Habitat Area for Target Species and Lifestages in UT-C

		Avg. Daily Habitat Area (acres) by Water Year Type		
Species	**Lifestage**	**Wet**	**Average**	**Dry**

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage. When two flows are indicated as providing 100 percent of habitat, the lower of the two flows was referenced in the text.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

TABLE 60
Average Daily Habitat Area for Target Species and Lifestages in UT-D

		Avg. Daily Habitat Area (acres) by Water Year Type		
Species	**Lifestage**	**Wet**	**Average**	**Dry**
Chinook Salmon	Spawning	5.49	5.84	3.61
	Juvenile	3.33	3.35	3.67
Chum Salmon	Spawning	13.39	16.54	16.75
Coho Salmon	Spawning	8.84	9.36	9.70
	Juvenile	2.10	2.06	2.28
Sockeye Salmon	Spawning	11.56	11.95	11.73
	Juvenile	1.47	1.39	1.39
Arctic Grayling	Spawning	10.77	11.36	16.51
	Juvenile	4.31	4.27	4.77
	Adult	3.14	3.13	3.12
Dolly Varden	Spawning	11.86	13.42	15.76
	Juvenile	2.17	2.11	2.40
	Adult	2.12	2.04	2.34
Rainbow Trout	Spawning	4.36	7.42	11.95
	Juvenile	4.02	4.02	4.04
	Adult	6.01	6.07	6.89

Note:

Provided during wet, average, and dry water year types, as determined from habitat duration analysis for UT-D, Upper Talarik Creek, Alaska.

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage. When two flows are indicated as providing 100 percent of habitat, the lower of the two flows was referenced in the text.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

TABLE 66
Average Daily Habitat Area for Target Species and Lifestages in UT-F

Species	Lifestage	Avg. Daily Habitat Area (acres) by Water Year Type		
		Wet	Average	Dry
Chinook Salmon	Spawning	0.72	0.31	0.17
	Juvenile	2.14	2.12	2.15

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

110	40.2	**88.3**	95.3	17.7	92.6	***91.8***	15.6	95.5	38.5
120	39.4	100.0	100.0	17.1	100.0	100.0	14.3	100.0	41.8

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage. When two flows are indicated as providing 100 percent of habitat, the lower of the two flows was referenced in the text.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

TABLE 69
Average Daily Habitat Area for Target Species and Lifestages in Tributary UT 1.190

		Avg. Daily Habitat Area (acres) by Water Year Type		
Species	**Lifestage**	**Wet**	**Average**	**Dry**

Notes:

Boxed values indicate the flow (as indicated in the far left column) that provides the maximum (100 percent) amount of habitat within the reach for a given species and lifestage. When two flows are indicated as providing 100 percent of habitat, the lower of the two flows was referenced in the text.

Bold italicized values indicate the flow (as indicated in the far left column) that provides approximately 90 percent of the maximum amount of habitat within the reach for a given species and lifestage.

TABLE 72
Average Daily Habitat Area for Target Species and Lifestages in the KR

		Avg. Daily Habitat Area (acres) by Water Year Type		
Species	**Lifestage**	**Wet**	**Average**	**Dry**
Chinook Salmon	Spawning	16.86	16.71	14.07
	Juvenile	20.92	20.66	19.74
Chum Salmon	Spawning	35.36	40.13	45.27
Coho Salmon	Spawning	39.04	39.45	43.21
	Juvenile	16.94	16.29	15.33
Sockeye Salmon	Spawning	40.33	44.53	49.49
	Juvenile	17.71	16.48	16.29
Arctic Grayling	Spawning	58.12	64.07	62.35
	Juvenile	28.21	28.07	27.60
	Adult	14.54	14.18	13.83
Dolly Varden	Spawning	42.95	52.24	65.60
	Juvenile	19.60	19.15	18.16
	Adult	20.58	20.06	18.59
Rainbow Trout	Spawning	19.17	23.19	31.80
	Juvenile	20.59	20.02	19.13
	Adult	24.47	24.77	25.17

Note:

Provided during wet, average, and dry water year types, as determined from habitat duration analysis for the KR, Mainstem Koktuli River, Alaska.

TABLE 73
Sum of Average Daily Habitat Area in Modeled Reaches of the NFK, SFK, UT, and KR

Species	Lifestage	Sum of Average Daily Habitat Area (acres)			
		NFK	SFK	UT	KR
Chinook Salmon	Spawning	19.3	23.5	17.9	16.7
	Juvenile	21.4	17.5	14.4	20.7
Chum Salmon	Spawning	63.1	57.9	47.3	40.1
Coho Salmon	Spawning	30.7	26.9	34.0	39.5
	Juvenile	27.5	13.9	13.9	16.3
Sockeye Salmon	Spawning	31.2	41.2	39.4	44.5
	Juvenile	19.4	12.3	10.7	16.5
Arctic Grayling	Spawning	33.4	29.1	46.1	64.1
	Juvenile	43.1	33.3	24.9	28.1
	Adult	12.3	10.4	11.0	14.2
Dolly Varden	Spawning	53.6	50.5	51.1	52.2
	Juvenile	26.8	20.6	14.8	19.2
	Adult	27.0	20.8	15.1	20.1
Rainbow Trout	Spawning	31.9	34.5	32.6	23.2
	Juvenile	19.3	16.3	15.6	20.0
	Adult	31.0	25.2	22.3	24.8

Note:

Provided for target species and lifestages in modeled reaches of each basin during average water year type, as determined from habitat duration analysis for the NFK, SFK, UT, and KR, Alaska.

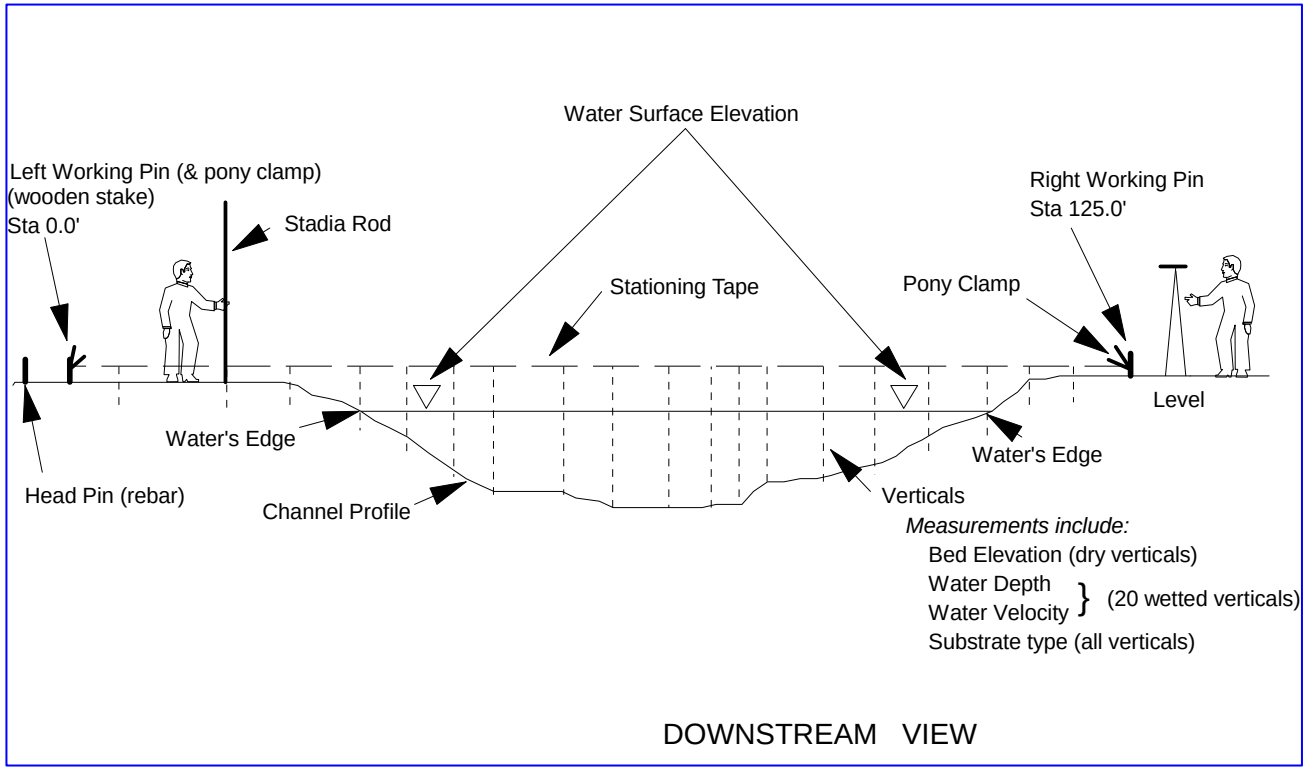

FIGURE 9
Example PHABSIM Cross-channel Transect

Note:
Illustrates representative transect setup and data-collection points across each transect. Head pins and/or tail pins were established on one or both sides of the river (head pins on the left side of the channel and tail pins on the right, looking downstream). The figure above only depicts head pins on the left bank; tail pins, if present, would be located to the right of the right working pin.

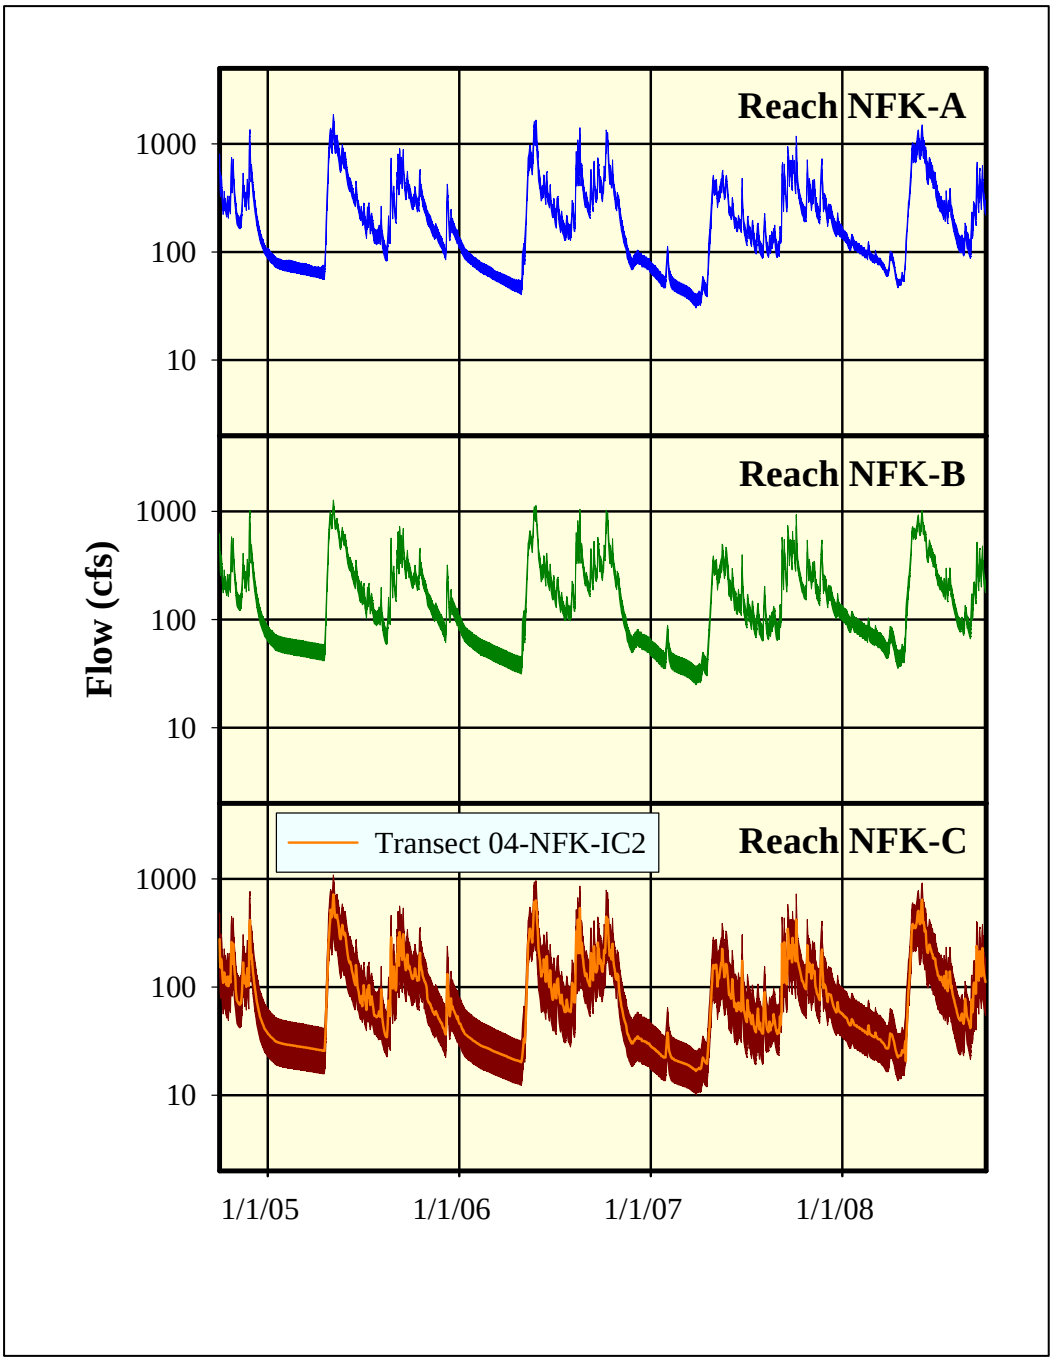

FIGURE 10
Range of Daily Flows and Interpolated Daily Flows in the NFK, October 2004 through September 2008

Note:

Range of daily measured flows NFK-A, NFK-B, and NFK-C and interpolated daily flows at IFIM Transect 04-NFK-IC2 at River Kilometer 33.65 in NFK-C, October 1, 2004, to September 30, 2008.

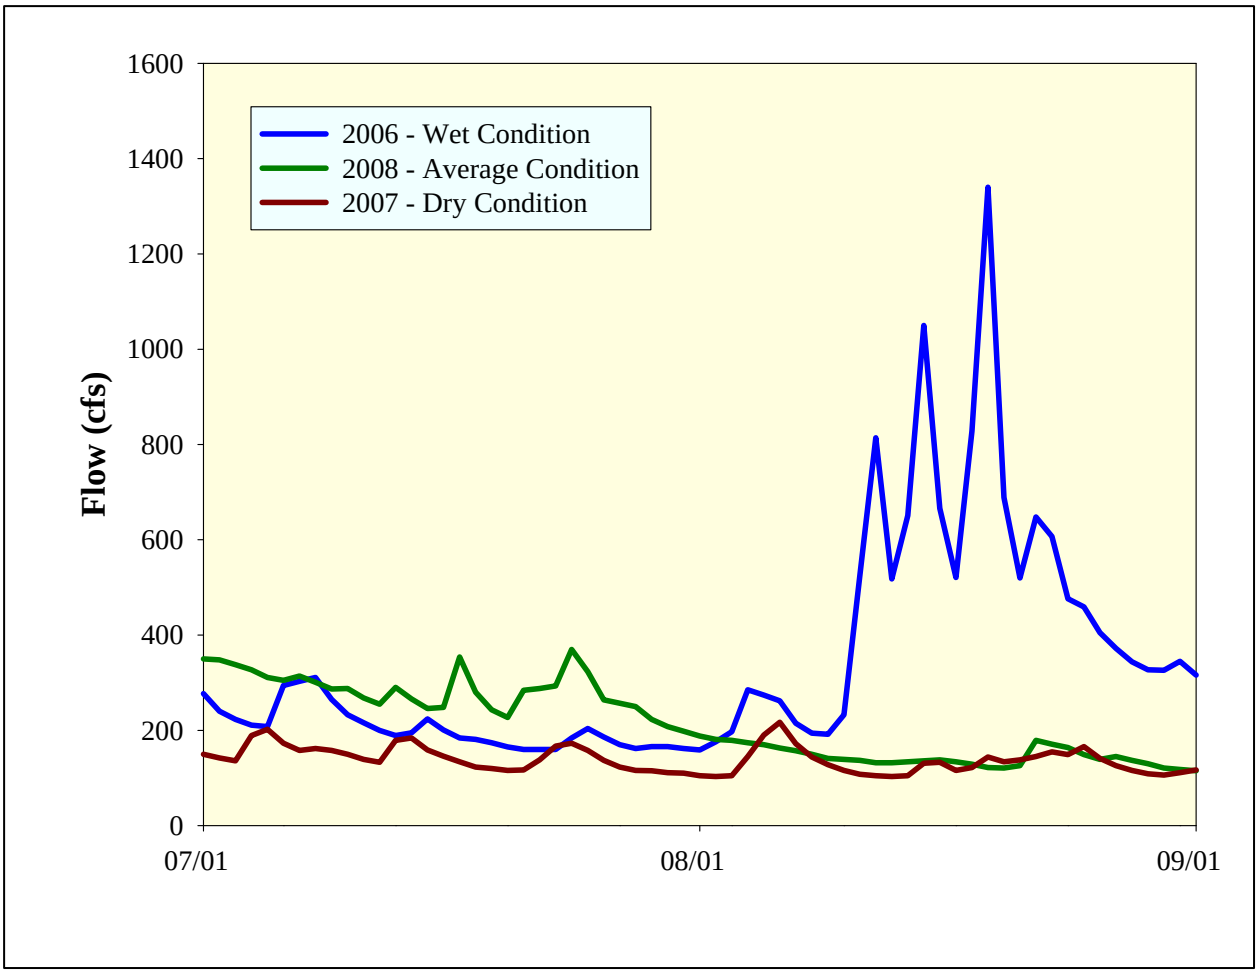

FIGURE 11
Wet, Average, and Dry Conditions in the NFK for Chinook Salmon Spawning from July to September, 2006 through 2008

1. INTRODUCTION AND BACKGROUND

The instream flow study for the Pebble Project was initiated in 2004 as part of environmental baseline studies. The area specific to the instream flow study includes the upper portion of the mainstem Koktuli River and the full lengths of the North Fork Koktuli River, South Fork Koktuli River, and Upper Talarik Creek. The basins represented by these streams are depicted in Figure 1. Studies completed in 2004, 2005 and 2007 resulted in the establishment and measurement of 92 transects for use in developing hydraulic models that can be linked to habitat models for deriving habitat:flow relationships. The distribution of these transects was respectfully, 5, 21, 28, 38 for the mainstem Koktuli River, North Fork Koktuli River, South Fork Koktuli River, and Upper Talarik Creek. In 2008, an additional 46 transects were established and measured, consisting of 17 transects on the North Fork Koktuli watershed, 18 in the South Fork Koktuli system, and 11 in Upper Talarik Creek. Collectively, these 138 transects will be used in developing habitat:flow relationships (based on **P**hysical **Hab**itat **Sim**ulation modeling – **PHABSIM;** Bovee 1982) that can then be applied in evaluating the effects related to changes in flow regimes. A more detailed discussion of the overall objectives of and methods used in conducting the instream flow study is found in the 2008 Instream Flow Study Plan (R2 2008). It should be noted that while the focus of the instream flow study is on the mainstem and major tributaries of each of the three drainages, separate studies are also underway designed to evaluate flow-habitat relationships in off-channel areas, flow-temperature relationships for each of the mainstem rivers, and fluvial geomorphologic considerations.

One of the major components in completion of the Pebble Project Instream Flow Study is the selection and use of species and lifestage Habitat Suitability Criteria (HSC) curves. HSC curves reflect species and lifestage use of selected habitat parameters (depth, velocity, substrate, and cover) (Bovee 1986). Depending on the extent of data available, HSC curves can be developed from the literature (Category 1 curves), or from physical and hydraulic measurements made in the field (i.e., site specific) over microhabitats utilized by the species (Category 2 curves – Utilization Curves). Site specific data most closely represent the conditions experienced by species directly within the streams of interest and therefore, to the extent possible, should be collected and used in developing HSC curves. When adjusted for availability, these latter curves may reflect species preference (Category 3 curves – Preference Curves) (Bovee 1986).

Since no HSC curves had been previously developed for fish species in the three rivers, site specific microhabitat data were collected by R2 Resource Consultants (R2) in 2008 and, previously, by HDR from 2005 to 2007. The intent was to focus data collection efforts on certain fish species because of their commercial, recreational, subsistence and ceremonial value.

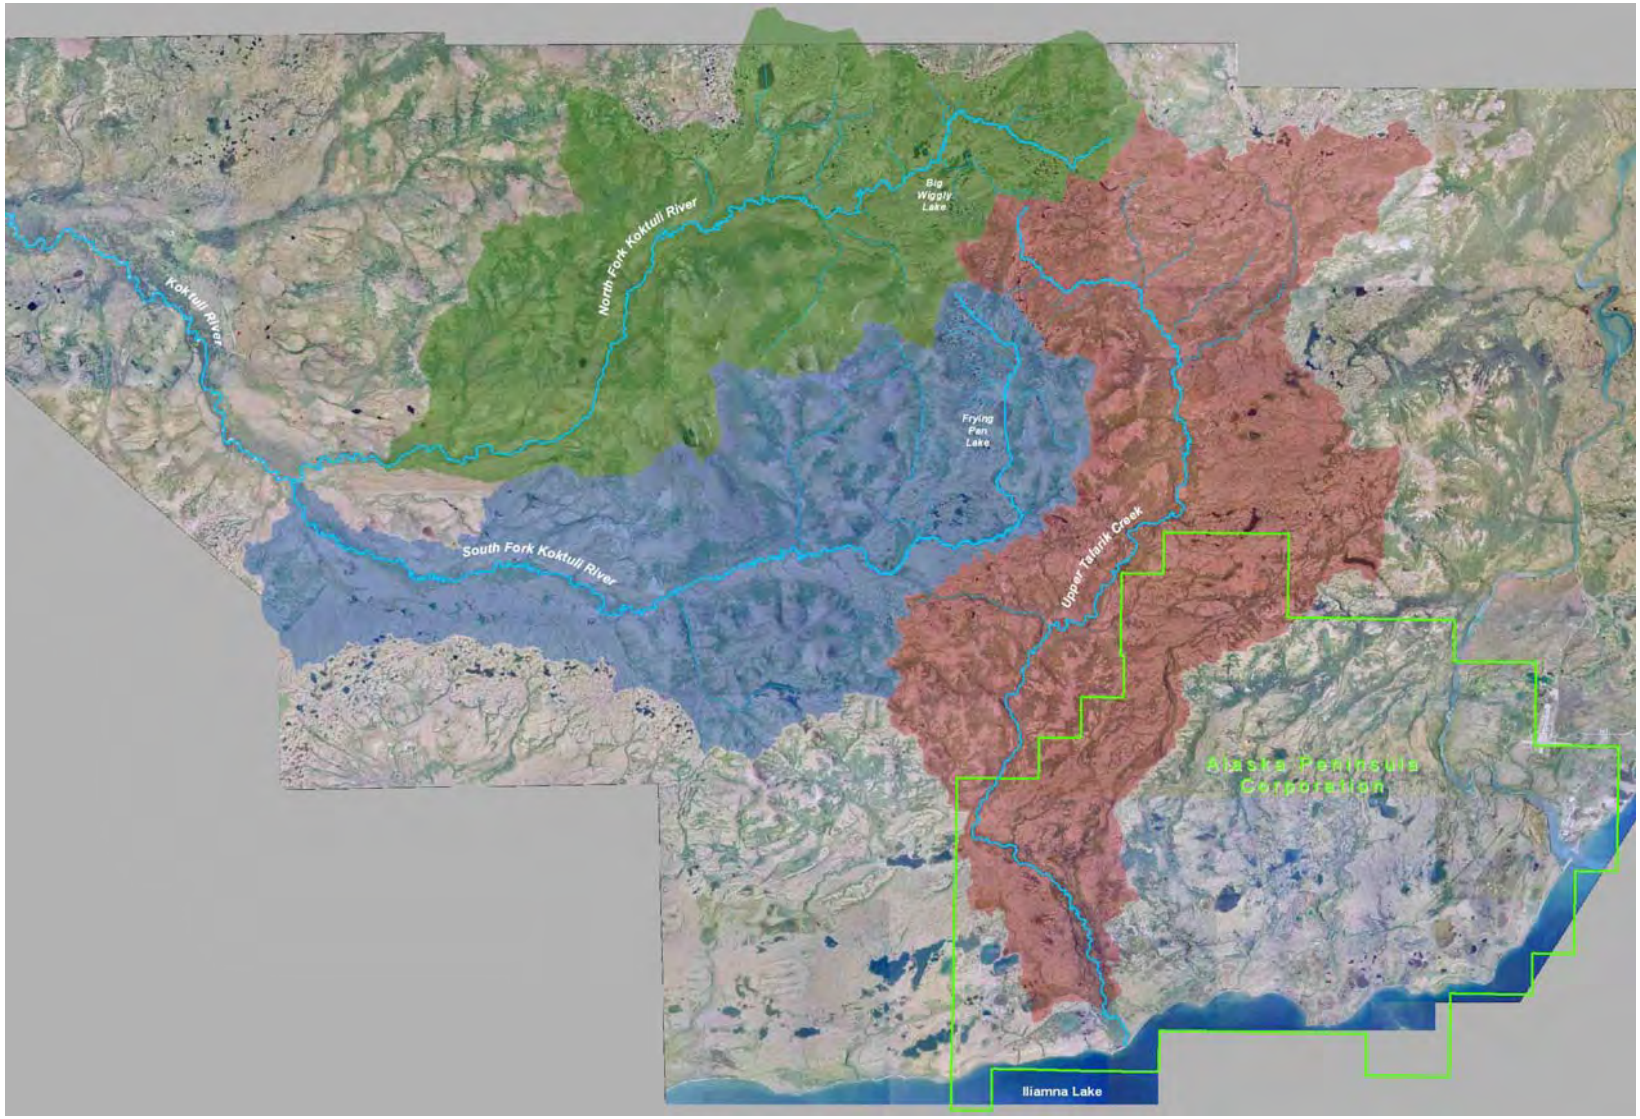

Figure 1. Site map showing primary basins within the Pebble Project: North Fork Koktuli River, South Fork Koktuli River, and Upper Talarik Creek.

These species are collectively termed target fish species and include:

- Sockeye salmon *(O. nerka*)
- Coho salmon *(Oncorhynchus kisutch)*
- Chinook salmon (*O. tshawytscha*)
- Chum salmon (*O. keta*)
- Rainbow trout (*O. mykiss*)
- Grayling (*Thymallus arcticus*)
- Dolly Varden (*Salvelinus malma*), and
- Round whitefish (*Prosopium cylindraceum).*

However, not all of these species are readily observable (given flow characteristics) or sufficiently abundant to allow collection of site specific data. Therefore, while the derivation of HSC curves for some of the target species will likely be based on site specific data, HSC curves for others may be based on a combination of site specific data and literature information.

1.1 OBJECTIVES AND PURPOSE OF THIS DOCUMENT

The main objective of this document is to provide HSC curves for each target species and lifestage for use in calculating the relationship between flow and potential habitat. The document is organized into the following 5 sections:

- **Section 1** – INTRODUCTION (this section): provides general background information of the instream flow study, the need for HSC curves, and the rationale for developing site-specific HSC curves for the Pebble Project.
- **Section 2** – METHODS: describes the general procedures used in both collecting and analyzing the site specific microhabitat data and developing candidate HSC curves;
- **Section 3** – RESULTS: summarizes the results of the HSC curve development process by species and lifestage;
- **Section 4** – CANDIDATE HSC CURVES: presents a set of candidate HSC curves for each of the target fish species and lifestages; and
- **Section 5** – REFERENCES.

2. METHODS

The Pebble Project HSC study focused on collecting data related to spawning habitat use, and juvenile (and adult – *for resident salmonids*) rearing habitat use. This section first describes the considerations that went into selection of study sites, and the timing of specific surveys, and then describes field data collection and analytical methods used in developing the HSC curves.

2.1 STUDY SITE SELECTION

Both the spawning and juvenile/resident surveys were conducted in all three basins associated with the Pebble Instream Flow Study, the North Fork Koktuli River, the South Fork Koktuli River, and Upper Talarik Creek (Figure 1). The North Fork Koktuli River and South Fork Koktuli River flow together into the Mainstem Koktuli River, a tributary to the Mulchatna River, which in turn is a tributary to the Nushagak River. Upper Talarik Creek flows directly into Lake Iliamna, which in turn flows into the Kvichak River.

The selection of study sites for collecting HSC microhabitat data was based on several factors, including:

- Representativeness of habitat types relative to other areas not sampled – wanted to sample areas that contained habitat features similar to other areas;
- Diversity of habitat types;
- Longitudinal location – spatial representation;
- Proximity of areas sampled to instream flow transects;
- Linkages with other fish studies; e.g., mainstem index site surveys and off-channel surveys;
- Flow conditions/visibility; and
- Accessibility and safe sampling conditions

2.2 SURVEY DATES

In 2008, R2 conducted surveys for targeted species/lifestages within the following range of dates:

- Coho salmon spawning – September 17-23, 2008
- Sockeye salmon spawning – August 5-9, 2008
- Chinook salmon spawning – August 5-7, 2008

- Chum salmon spawning – August 5-6, 2008
- Juvenile/resident rearing – August 18-22, 2008

HDR conducted surveys from 2005 to 2007 for various species lifestages during the following range of dates:

- Sockeye salmon spawning – July 24 – August 6, 2005 and August 3-8, 2006,
- Chinook salmon spawning – July 24 – August 6, 2005 and August 3-8, 2006,
- Juvenile/resident rearing – June 21 – July 19, 2007

The dates of these surveys were based in part on a generalized periodicity chart that depicts the timing of habitat use of anadromous and resident salmonid species for different lifestages within the three drainages (Figure 2). The periodicity information as presented in Figure 2 was based on available data at the time of its development and will be updated based on results of ongoing fish studies. The periodicity information was used for planning purposes to assist in determining approximate dates when field surveys should be conducted that would allow the best opportunity to observe target fish species and lifestage activity.

2.3 ANADROMOUS SPAWNING SURVEYS

The timing and location of spawning surveys were based in part on the periodicity data as well as information obtained during aerial (helicopter) spawner escapement surveys conducted by R2. Active spawning locations were identified by R2 staff during helicopter surveys of each stream. This information was used to identify areas with the highest concentration of spawning activity for the four main salmon species (sockeye, coho, Chinook, and chum salmon).

Figure 2. General periodicity chart for target fish species in the North Fork Koktuli River, South Fork Koktuli River and Upper Talarik Creek.

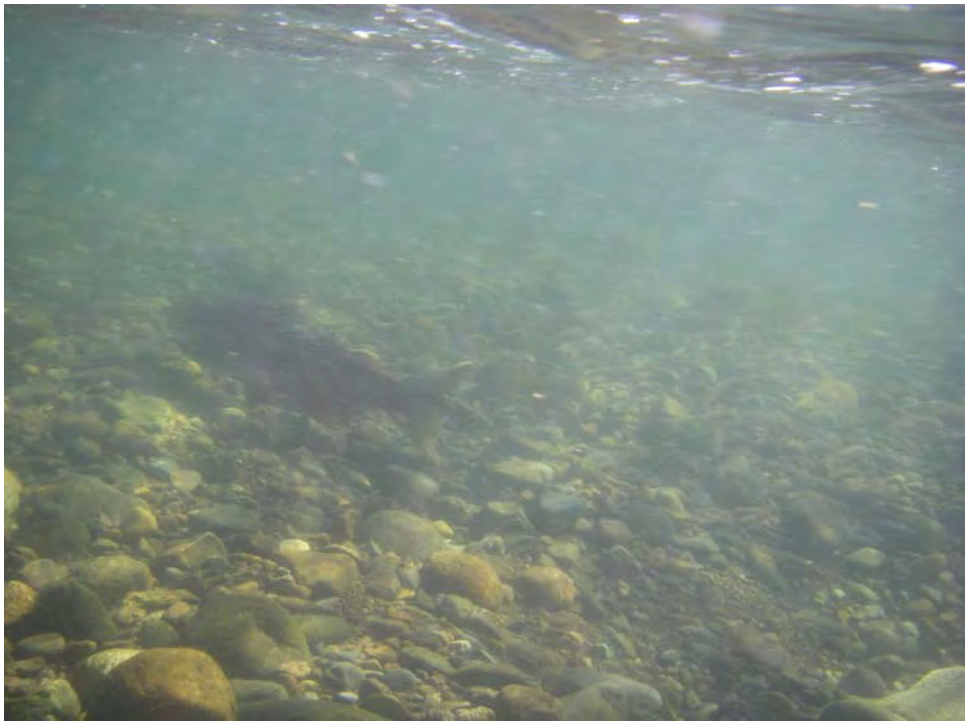

Figure 3. Example of a typical redd observed during spawning surveys. Depth, velocity, substrate, and redd dimensions were measured at each redd.

2.4 SNORKEL SURVEYS – JUVENILE AND RESIDENT REARING

Snorkel surveys were conducted by a team of two or three fish biologists with extensive experience in salmonid species identification. These surveys were conducted in conjunction with mainstem index surveys that were designed to systematically sample fish assemblages within representative sections of each stream. In general, the steps used in completing these surveys included:

1. ***Survey Preparation*** – All field equipment used for collecting microhabitat data was checked and assembled for use. This included completing a test of calibrated velocity meters, and assembling/gathering the top setting rod, marking weights and/or flagging, underwater lights, and dry suits. Stream flows were monitored on the day of the survey to ensure stable flow conditions during sampling.
2. ***Sampling Conditions/Visibility Assessment*** – Prior to each survey, a secchi disk reading was taken to determine the visibility corridor for sampling. For this, a secchi disk was held underwater by the data recorder, and a tape measure extended by the snorkeler from the secchi disk outward to a point where the disk is no longer clearly visible (Figure 4). As a rule, when visibility conditions were less than four feet, no sampling occurred. Water temperature was also recorded at the beginning of each survey.

To ensure accurate estimation of fish size underwater, the snorkelers calibrated their sight to a ruler prior to beginning each survey. Rulers and objects of known length (e.g., fingers, marks on diving gloves) were used during the survey to maintain accuracy in the estimation of fish length.

3. ***Snorkel Survey/Fish Observations*** – Starting at the lower/downstream point within a study site, the snorkelers proceeded in an upstream direction making observations of all microhabitat types within their line of sight (Figure 5). When two divers were working together, both sides of the river were covered, with the midpoint of the river serving as the delineation point of coverage for each diver. When only a single diver was conducting the survey, the diver surveyed one or both sides of the river, depending on the range of microhabitats present. When a fish was observed the snorkeler verbally transmitted the following information to the data recorder:
    - Fish species
    - Fish length (mm)
    - Location in water column (distance from the bottom)
    - Substrate use classification
    - Proximity/affinity to habitat structure/cover features (e.g., boulder, undercut bank, overhanging vegetation, large woody debris)
    - Relevant comments pertaining to cover associations and/or behavioral characteristics of the fish observed

Only fish holding over a fixed position were included in the microhabitat survey. Moving fish were not enumerated in order to minimize inaccurate habitat measurements, and to prevent double-counting of fish. Locations of observed fish were marked with a weight or flagging.

4. ***Microhabitat Measurements*** – Subsequent to locating a fish observation, the data recorder proceeded to the fish location and collected the following information:
    - Water depth – measured to the nearest 0.1 feet using a top setting rod
    - Mean column velocity (fps) – measured using a Swoffer Model 2100 or Marsh McBirney FlowMate 2000 current meter (Figure 6)
    - Substrate classification – dominant/sub-dominant

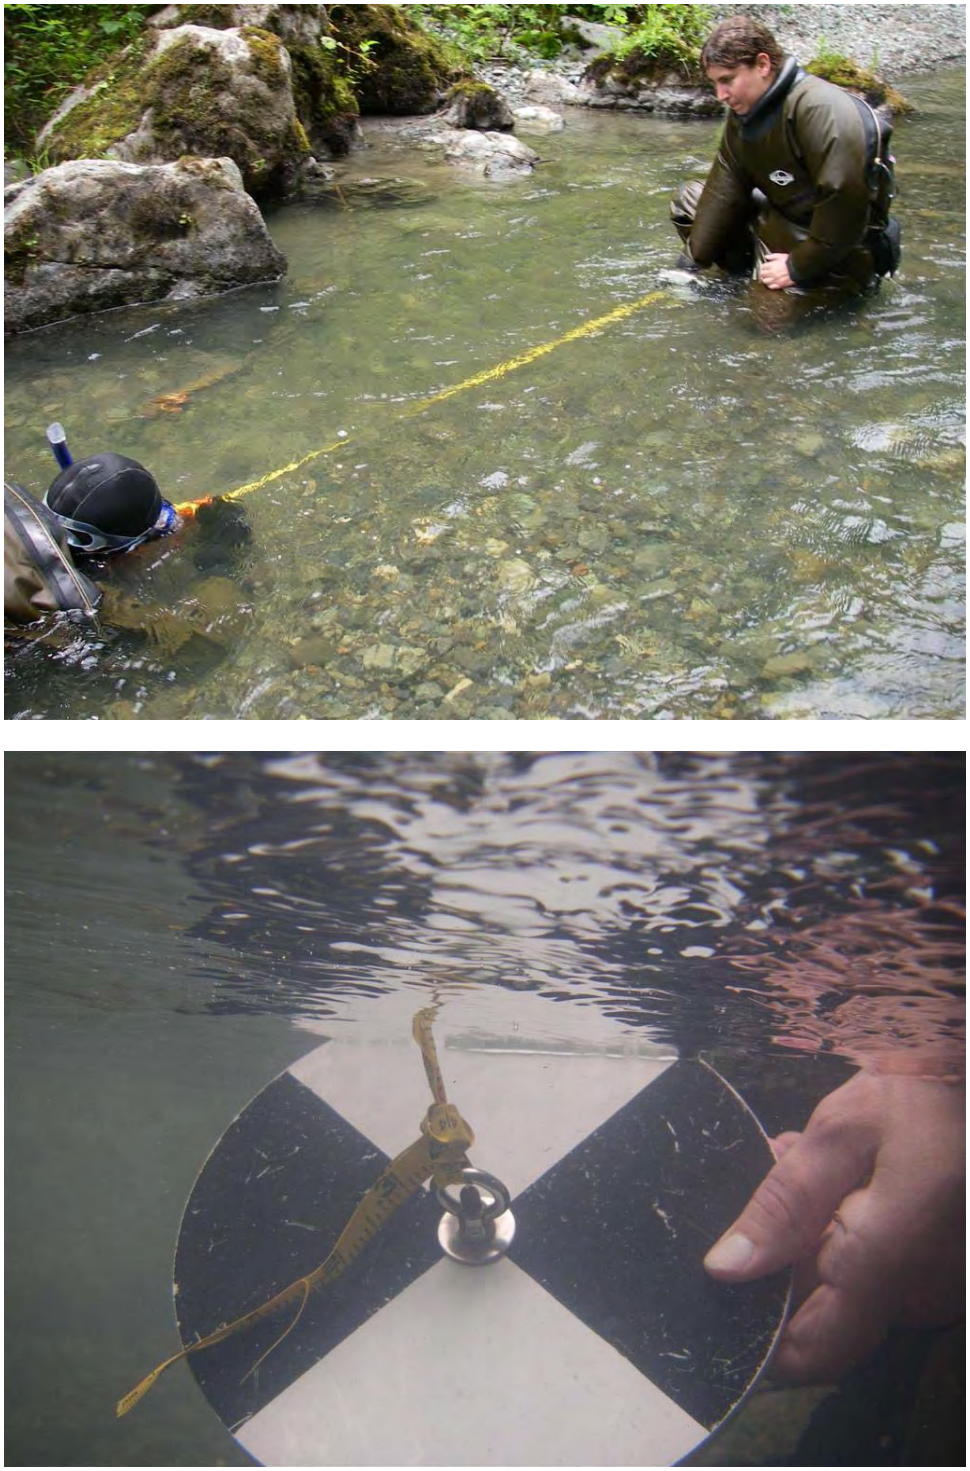

Figure 4. Visibility conditions were assessed using a secchi disk prior to conducting microhabitat snorkel surveys.

Figure 5. Photograph of snorkeler making fish observations along streambank. Locations where fish were observed were marked with a weight or flagging.

Figure 6. Depth and velocity measurements were taken at locations where fish were observed.

All data were recorded on waterproof data sheets; the data were reviewed in the field to ensure that all measurements were properly recorded and were legible prior to departure. Digital photographs were taken of representative habitat types where fish of different species and size classes were observed.

2.5 FLOW CONDITIONS

The quantity and rate (cubic feet per second) of flow within each stream during the time of fish use, to a large degree, determines the distribution of microhabitat (depth and velocity) combinations that are available to fish. Stream flow records for each basin are available from USGS continuous flow monitoring stations. These are depicted below for the North Fork Koktuli River – (USGS Gage 15302250) (Figure 7), South Fork Koktuli River – (USGS Gage 1530220) (Figure 8), and Upper Talarik Creek – USGS Gage 15300250) (Figure 9).

Dates of the microhabitat surveys completed by R2 in 2008 for spawning and rearing were superimposed on the flow records as a means to assess the relative stability of flows during the surveys. In general, the surveys in August (Chinook and sockeye salmon spawning, and juvenile and fry rearing) were completed under relatively stable flow conditions, while those in September (coho salmon spawning) were completed under more variable conditions. No comparison of flow conditions and survey dates was completed for the HDR data sets since data were collected during three separate years.

2.6 DATA ANALYSIS

Prior to calculation of the HSC curves, the habitat data from each stream were organized by species and lifestage, entered into commercially available spreadsheets, and subsequently checked for data entry accuracy. Frequency distributions were then generated for mean velocity, depth, and substrate type for each species and then normalized. Histogram plots of depth and mean column velocity utilization were produced using a 0.2 bin width. For species/lifestages for which sufficient observations were collected ($n \geq 20$), the frequency distribution of the field observations was then converted to suitability by scaling the distribution between 0 and 1 (utilization values divided by the maximum value observed). The resulting curves were inspected and visually adjusted, in part to smooth out sharp breakpoints, and in the case of depth, extend the range of the curve to reflect a non-limiting condition.

For comparative purposes, HSC curves for each species and lifestage were first developed using pooled data from all three streams, and then separate curves were developed based on stream-specific data. Thus, for certain species and lifestages (e.g., sockeye and coho salmon spawning) four separate HSC curves were generated, one based on combined data, one based on data for North Fork Koktuli, one for South Fork Koktuli, and one for Upper Talarik Creek.

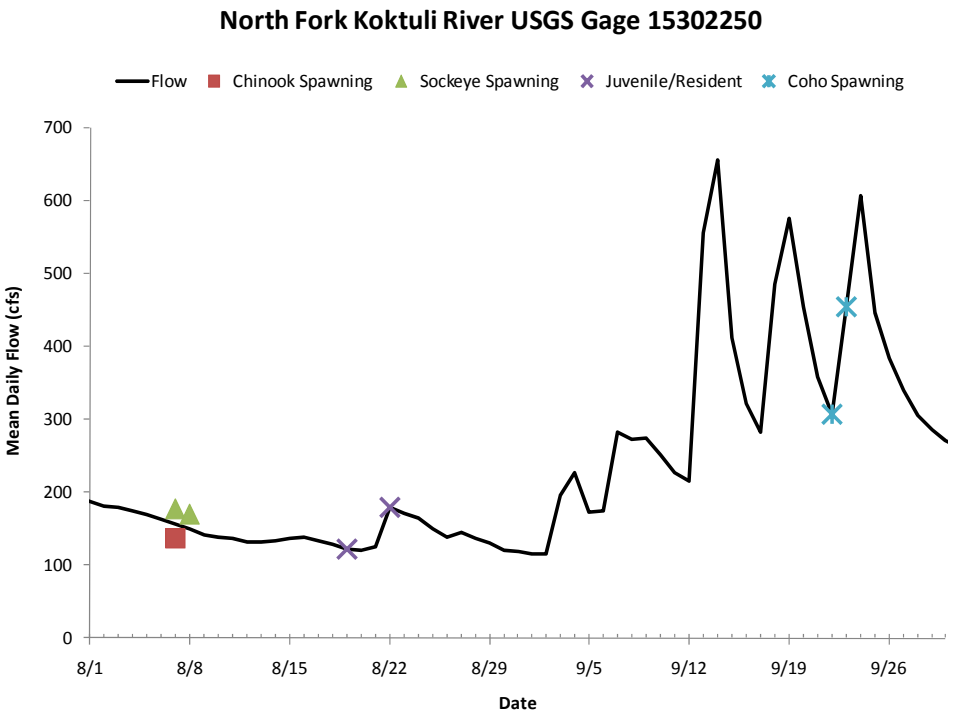

Figure 7. Average daily flows in the North Fork Koktuli River from August 1 – September 30, 2008 during microhabitat surveys. Points indicate the first and last survey date for each species/lifestage.

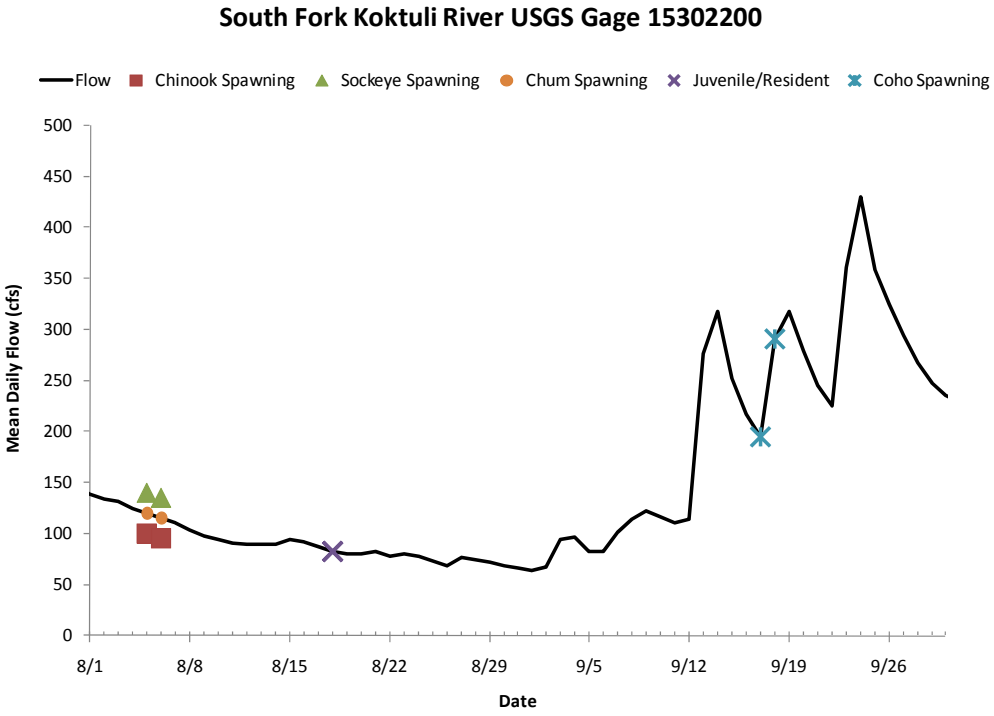

Figure 8. Average daily flows in the South Fork Koktuli River from August 1 – September 30, 2008 during microhabitat surveys. Points indicate the first and last survey date for each species/lifestage.

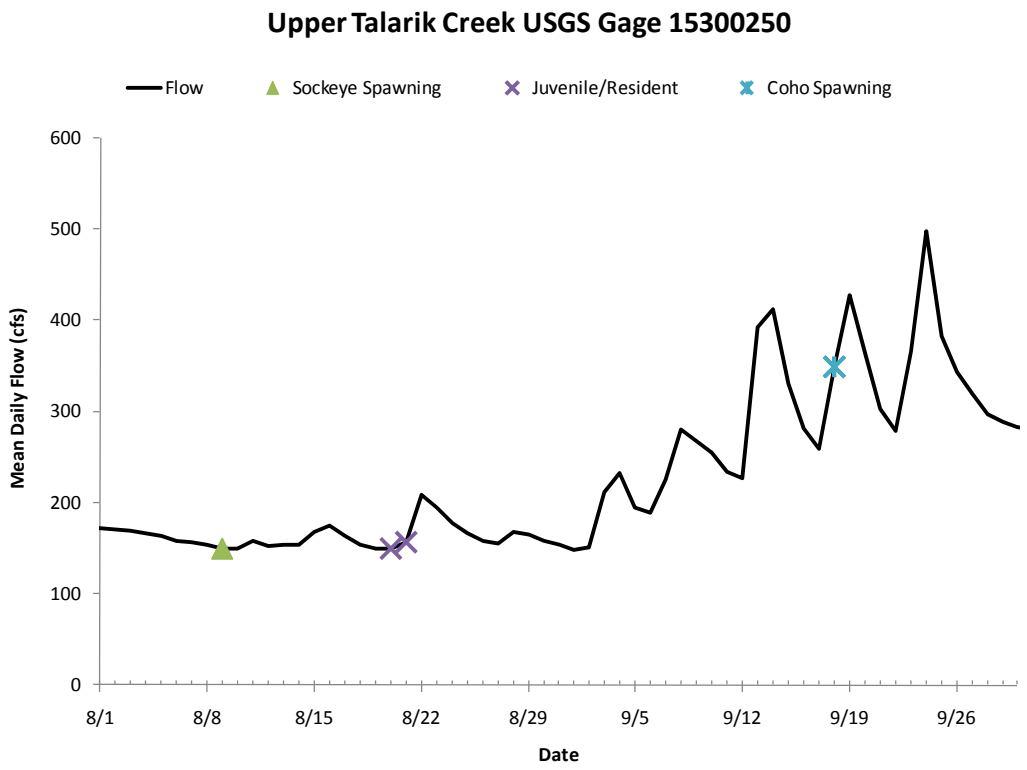

Figure 9. Average daily flows in the Upper Talarik Creek from August 1 – September 30, 2008 during microhabitat surveys. Points indicate the first and last survey date for each species/lifestage.

3. RESULTS

This section presents the results of the microhabitat surveys completed on each of the three basins from 2005 to 2008 which are summarized in Table 1 by species, lifestage, basin, and source (R2 or HDR). Overall, a total of 1,329 distinct measurements of habitat utilization were made on eight of the target fish species; sockeye, coho, Chinook, and chum salmon, rainbow trout, Dolly Varden, grayling, and round whitefish. The largest number of observations was made for sockeye salmon (n=494) (spawning and juvenile), followed by coho salmon (n=407) (spawning, fry, and juvenile), and Chinook salmon (n=286) (spawning, fry, and juvenile). The spatial distribution of these measurements is depicted in Figures 10 through 12.

The results provided below are organized by lifestage and provide a brief summary of the habitat characteristics (depth, velocity, and substrate) observed for various target species.

3.1 SALMON SPAWNING SURVEYS

From 2005 to 2008, R2 and HDR collected measurements from 753 redds. Of these, 509 observations were made by R2 in 2008. The following are brief summaries of the redd measurements made for each species.

For coho salmon, 98 redds were observed. Nearly all of these observations (n = 95) were made in the North Fork Koktuli River and South Fork Koktul River (Figure 10). Water depths, as measured at the upstream end of each redd, ranged from 0.50 to 3.00 ft with a median of 1.30 ft and an average of 1.45 ft. Mean column water velocities, again as measured at the upstream end of each redd, ranged from 0.04 to 4.75 ft/s with a median of 2.11 ft/s and an average of 2.08 ft/s. Redd substrate size ranged from small gravel to small cobble, but large gravel was the dominant size for the majority (94%) of redds.

For sockeye salmon, 475 redds were observed. Approximately equal numbers of observations were made in each of the three basins (Figure 11). Water depths ranged from 0.30 to 2.50 ft with a median of 1.00 ft and an average of 1.06 ft. Water velocities ranged from 0.00 to 4.25 ft/s with a median of 1.91 ft/s and an average of 1.84 ft/s. The dominant redd substrate size ranged from fine material to large cobble, but large gravel was the dominant substrate size for the majority (77%) of redds.

Table 1. Summary of microhabitat measurements made by R2 and HDR in the North Fork Koktuli River, South Fork Koktuli River, and Upper Talarik Creek by species and lifestage. Data collected from 2004 to 2008.

* includes two redds from mainstem Koktuli River

For Chinook salmon, 173 redds were observed. Two redds were observed in the mainstem Koktuli River just downstream of the confluence, and the remainder were observed in the North Fork Koktuli River (n = 96) and South Fork Koktuli River (n = 75) (Figure 12). Water depths ranged from 0.85 to 3.50 ft with a median of 1.60 ft and an average of 1.63 ft. Water velocities ranged from 1.11 to 4.22 ft/s with a median of 2.67 ft/s and an average of 2.65 ft/s. The dominant redd substrate size ranged from small gravel to large cobble, but small cobble (59%) and large gravel (35%) were the dominant sizes for the majority of redds.

For chum salmon, only seven redds were observed, all in the South Fork Koktuli River. Water depths ranged from 0.90 to 1.80 ft with a median of 1.05 ft and an average of 1.17 ft. Water velocities ranged from 0.97 to 2.56 ft/s with a median of 1.57 ft/s and an average of 1.65 ft/s. The dominant redd substrate size included small gravel (57%) and large gravel (43%).

3.2 SALMON JUVENILE/FRY SNORKEL SURVEYS

From 2005 to 2008, R2 and HDR collected measurements from 441 juvenile salmon and resident fish observations. Of these, 295 observations were made by R2 in 2008. For juvenile fish, R2 made a distinction between fry and "juveniles" based on lengths estimated during snorkel surveys and using site-specific length/age class determinations. HDR did not distinguish between fry and "juveniles." Thus, juvenile data collected by R2 and discussed below excludes fry, whereas juvenile data collected by HDR may include fry observations.

For coho salmon, 221 juvenile (≥55 mm) observations were made. The water depth at each observation ranged from 0.30 to 3.30 ft with a median of 1.20 ft and an average of 1.33 ft. Mean column water velocities measured at each observation ranged from 0.00 to 2.67 ft/s with a median of 0.26 ft/s and an average of 0.42 ft/s. Eighty-eight coho salmon fry (<55 mm) observations were also made; water depths ranged from 0.40 to 4.5 ft with a median of 1.40 ft and an average of 1.6 ft. Water velocities for coho salmon fry observations ranged from 0.00 to 2.37 ft/s with a median of 0.29 ft/s and an average of 0.48 ft/s.

For sockeye salmon, 19 juvenile (>60 mm) observations were made. The water depth at each observation ranged from 0.30 to 1.60 ft with a median of 0.80 ft and an average of 0.88 ft. Mean column water velocities measured at each observation ranged from 0.00 to 1.35 ft/s with a median of 0.07 ft/s and an average of 0.26 ft/s. No sockeye salmon fry (≤60 mm) were observed.

For Chinook salmon, 94 juvenile (≥65 mm) observations were made. The water depth at each observation ranged from 0.20 to 3.6 ft with a median of 1.20 ft and an average of 1.34 ft. Mean column water velocities measured at each observation ranged from 0.00 to 3.01 ft/s with a median of 0.30 ft/s and an average of 0.52 ft/s. Nineteen Chinook salmon fry (<65 mm) observations were also made; water depths ranged from 0.50 to 3.5 ft with a median of 1.30 ft

and an average of 1.53 ft. Water velocities for Chinook salmon fry observations ranged from 0.00 to 2.61 ft/s with a median of 0.32 ft/s and an average of 0.57 ft/s.

3.3 RESIDENT SALMONID ADULT/JUVENILE/FRY SNORKEL SURVEYS

Microhabitat measurements of resident species were sparse compared to anadromous species. For rainbow trout, only eight adult (≥143 mm) observations of habitat use were made. The water depth at each adult observation ranged from 0.60 to 4.50 ft with a median of 3.90 ft and an average of 3.40 ft. Mean column water velocities ranged from 0.78 to 2.52 ft/s with a median of 2.09 ft/s and an average of 1.96 ft/s. Only nine juvenile rainbow trout (56 to 142 mm) observations were made; water depths ranged from 0.50 to 1.8 ft with a median of 0.90 ft and an average of 1.09 ft. Water velocities for rainbow trout juvenile observations ranged from 0.24 to 1.34 ft/s with a median of 0.32 ft/s and an average of 0.57 ft/s. Twenty-three rainbow trout fry (≤55 mm) observations were made; water depths ranged from 0.30 to 1.70 ft with a median of 0.70 ft and an average of 0.82 ft. Water velocities for rainbow trout fry ranged from 0.04 to 2.01 ft/s with a median of 0.44 ft/s and an average of 0.48 ft/s.

For grayling, 40 adult (> 160 mm) observations were made. The water depth at each adult observation ranged from 0.80 to 4.50 ft with a median of 3.35 ft and an average of 3.16 ft. Mean column water velocities ranged from 0.60 to 3.47 ft/s with a median of 1.56 ft/s and an average of 1.80 ft/s. Twenty-four juvenile grayling (56 to 160 mm) observations were also made; water depths ranged from 0.25 to 2.35 ft with a median of 0.70 ft and an average of 1.05 ft. Water velocities for juvenile grayling observations ranged from 0.02 to 1.90 ft/s with a median of 0.39 ft/s and an average of 0.50 ft/s. No grayling fry (≤55 mm) were observed.

For Dolly Varden, 16 juvenile (60 to 154 mm) observations were made. The water depth at each juvenile observation ranged from 0.60 to 4.50 ft with a median of 3.90 ft and an average of 3.40 ft. Mean column water velocities ranged from 0.78 to 2.52 ft/s with a median of 2.09 ft/s and an average of 1.96 ft/s. Only three Dolly Varden fry (<60 mm) and one adult (≥155 mm) were observed.

For whitefish (presumably round whitefish), 10 adult observations were made. No length/age-class determinations were available for whitefish. However, all observed fish were at least 225 mm in length and were therefore presumed to be adults. The water depth at each adult observation ranged from 2.25 to 4.20 ft with a median of 3.40 ft and an average of 3.46 ft. Mean column water velocities ranged from 1.15 to 2.83 ft/s with a median of 1.47 ft/s and an average of 1.71 ft/s. No whitefish juvenile or fry were observed.

4. CANDIDATE HSC CURVES

From 2004 to 2008, 1,328 site specific microhabitat utilization measurements were collected for the eight target fish species. The overall objective of the surveys was to collect sufficient numbers of data points from which to generate site specific HSC curves for use in PHABSIM modeling. In general, the greater the number of observations, the more reliable the data set from which to derive the HSC curves. Researchers often use the rule of thumb of having 75-150 observations from which to base curves, but fewer observations can also be used provided they are representative of a range of habitat types. For example, the Washington Department of Fish and Wildlife (WDFW) has developed HSC curves using as few as 25 observations (WDFW and WDOE 2008). Curves developed using fewer than 75 observations can also be used for making comparisons with literature derived curves to see if utilization trends are similar and for making suggested modifications.

In this study, species and lifestages for which ≥ 75 observations were made based on combined measurements and individual stream measurements included:

- Combined Measurements (all three basins):
  - Spawning – coho salmon (n=98), sockeye salmon (n=475), Chinook salmon (n=173)
  - Juvenile – coho salmon (n=221), Chinook salmon (n=94)
  - Fry – coho salmon (n=88)
- North Fork Koktuli River:
  - Spawning – sockeye salmon (n=162), Chinook salmon (n=96)
- South Fork Koktuli River:
  - Spawning – sockeye salmon (n=164), Chinook salmon (n=75)
- Upper Talarik Creek:
  - Spawning – sockeye salmon (n=149)
  - Juvenile – coho salmon (n=129)

Candidate HSC curves for each of the above species and lifestages are presented below. The curves include normalized frequency distributions of each parameter overlaid with the candidate HSC curve. The HSC curves generally track the shapes of the histograms. Maximum depth is not generally considered a limiting factor for fish habitat use. Therefore, in the HSC depth curves, depth was considered non-limiting and there is no descending limb on the HSC depth curves.

For discussion purposes and to aid in the selection of final HSC curves, curves were also developed and are presented below for certain species and lifestages for which < 75 observations were made. These included both anadromous and resident target fish species and included:

- Combined Measurements (all three basins):
  - Juvenile – sockeye salmon (n=19), grayling (n=24)
  - Fry – Chinook salmon (n=19), rainbow (n=23),
  - Adult – grayling (n=40)
- North Fork Koktuli River:
  - Spawning – coho salmon (n=52)
- South Fork Koktuli River:
  - Spawning – coho salmon (n=43)

The candidate HSC curves are presented below in Figures 13 through 36 with anadromous salmonids presented first, organized by lifestage – spawning → juvenile→ fry. In all cases, the curves for a given species and lifestage based on all data combined are presented first, followed by stream-specific curves.

Habitat - Flow Relationships

Attachment 2

Habitat:Flow Relationships

(Weighted Usable Area curves)

This document presents the habitat:flow relationships (i.e., Weighted Usable Area or WUA curves) for all PHABSIM (a physical habitat simulation software computer program) transects in the four study area basins: North Fork Koktuli (NFK), South Fork Koktuli (SFK), Upper Talarik Creek (UT), and Mainstem Koktuli River (KR). The WUA curves are plotted for adult rearing, spawning, and juvenile rearing of seven target species (Chinook, chum, coho, and sockeye salmon, and arctic grayling, Dolly Varden, and rainbow trout) for 30 transects on NFK, 43 transects on SFK, 40 transects on UT, and four transects on KR. These curves are provided Attachment 2, Supplement 1.

(A) WUA Development

Habitat modeling was completed using the HABTAV habitat simulation program of DOS PHABSIM Version 2.1. The HABTAV program uses velocities and depths from the hydraulic modeling output (IFG4) in conjunction with the habitat suitability criteria (HSC) to calculate the habitat area for each target species and lifestage over a range of flows (Milhous et al. 1989).

Habitat quantity from the HABTAV model is expressed as an index called Weighted Useable Area (WUA) and is given in square feet of habitat per 1,000 feet of stream length. Figure 1 illustrates the technique used in HBATAV for calculating habitat area. The habitat program uses the two midway points (the dashed lines) between measurement verticals (solid lines) to represent a cell. A measurement vertical is where the velocity, depth, and substrate code are measured. The same definition of a cell is used by the USGS (U.S. Geological Survey) for flow measurement and calculation (Rantz, 1982).

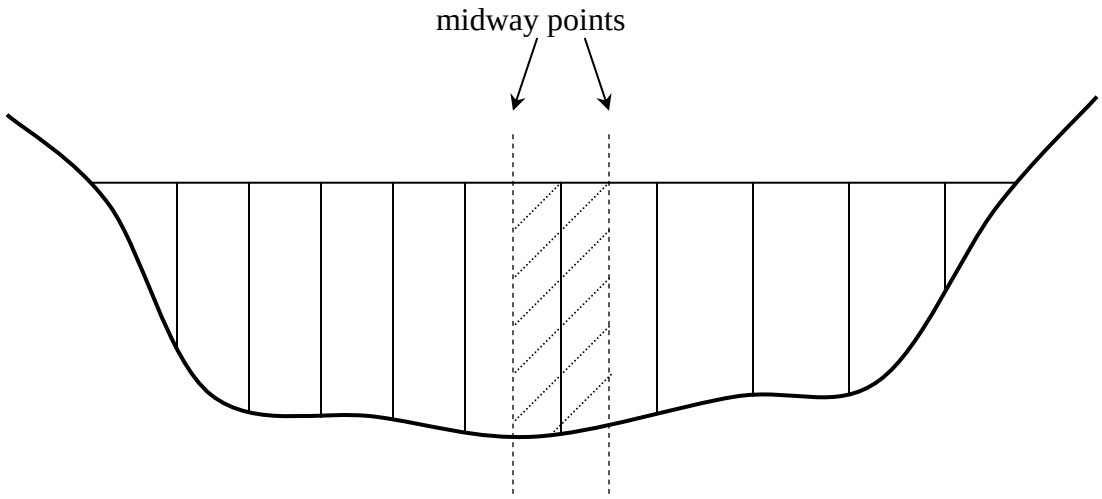

Figure 1.
The HABTAV habitat model cell boundary. The solid vertical lines are locations where velocity, depth, and substrate code are measured. The width of the hatched rectangle is the portion of the wetted width represented by the velocity/depth at the measurement vertical.

Prior to the habitat modeling, a Water Surface Elevation – Discharge (WSE~Q) rating curve is developed from the hydraulic modeling, as described in Appendix 15.1C, Attachment 4. The rating curve consists of 30 flows, and for each flow the habitat model was used to calculate a WUA value. The range of the 30 flows is designed to extend from minimum extrapolated flow (0.4 * lowest measured flow) to maximum extrapolated flow (2.5 * highest measured flow) Figure 2.

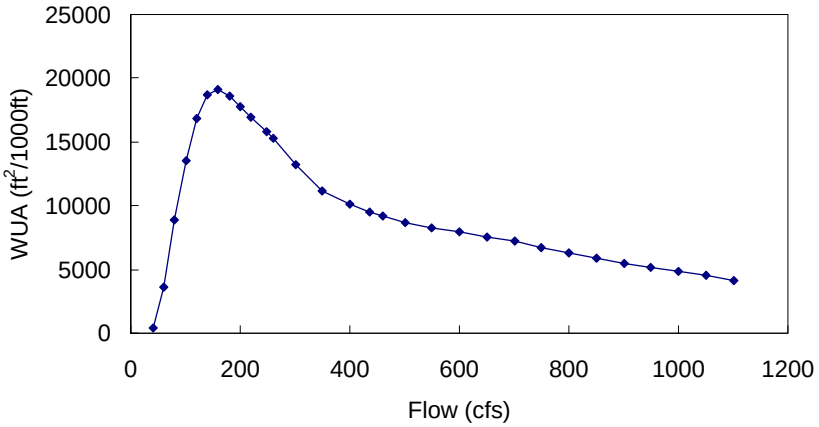

Figure 2.
A typical WUA~Q relationship consists of 30 flows, extending from minimum extrapolated flow to maximum extrapolated flow.

(B) Transect Composite WUA

In this study, each transect had multiple measured velocity profiles recorded at different flow conditions (e.g., low, mid, high flows). Each measured velocity profile is associated with a calibrated velocity profile from hydraulic modeling (see Appendix 15.1C, Attachment 4 for more details of velocity calibration), and the calibrated velocity profile is used by the habitat program to develop the WUA curve.

The shape of the velocity distribution across the transect may be significantly different under different flow conditions, and therefore each calibrated velocity profile can only be used to simulate the velocity profiles for flows near the measured flow. The velocity distributions are generally more uniform across the transect at higher flows. When flows are low, the velocities are affected more by the stream morphology and bed substrate, resulting in less uniform and spikier velocity profiles.

Due to different flow conditions of each measured flow, the WUA curve developed from each calibrated velocity profile may be different depending on which measured flow condition was used to calculate the WUA curve. Therefore, a composite curve is required to blend the multiple WUA curves to become a single habitat:flow curve for the transect.

Figure 3 is an example illustrating the process used to blend two WUA curves together to develop a single composite WUA curve for the transect. In this example there are only two flows used to develop the composite WUA curve, a low flow (Q_{low}) and a high flow (Q_{high}). While most transects typically have three or more measured velocity profiles available, only two flows are used here to illustrate the process.

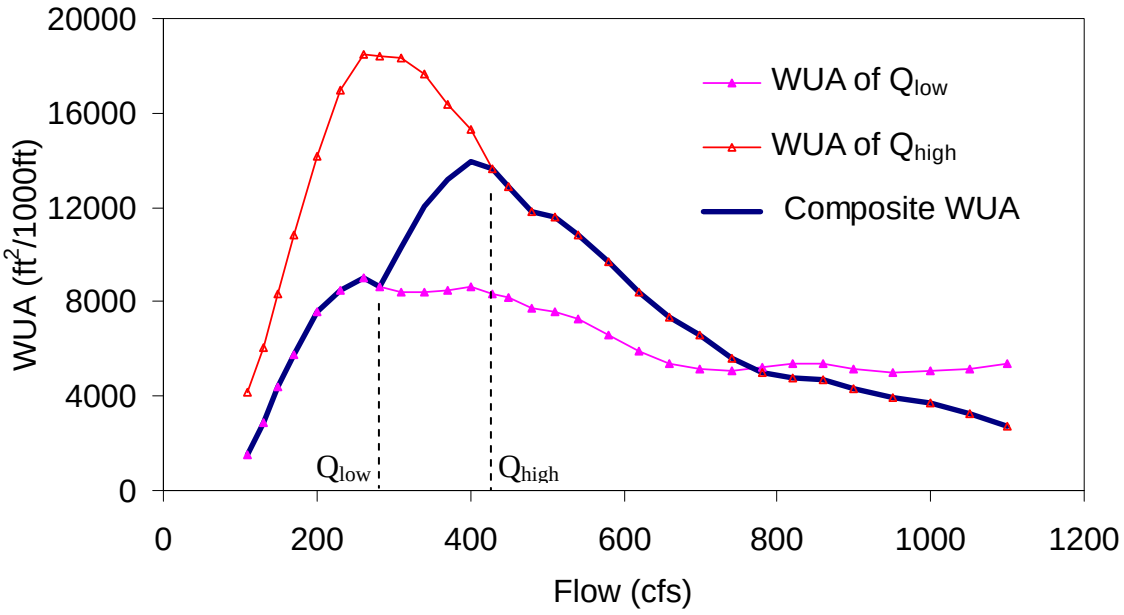

Figure 3.
Composite WUA for a transect with two measured flows. The line with solid triangles represents WUA calculated from low flow measurement. The line with hollow triangles line represents WUA calculated from high flow measurement. The thick blue line is the composite WUA curve for the transect. The maximum habitat value of the composite curve and the flow at which maximum habitat occurs may be different from the original WUA curves.

The line with solid triangles represents the weighted usable area for Q_{low} (i.e., the WUA curve developed from the calibrated velocity profile of Q_{low}), the line with hollow triangles represents the weighted usable area for Q_{high}, and the thick blue line is the composite WUA curve. For flows lower than Q_{low}, the line with solid triangles is used for the composite curve, and for flows greater than Q_{high}, the line with hollow triangles is used. For flows between the two measured flows, a weighting factor is used to blend the two curves together. The weighting factor, F, is determined using the flows, and it is defined as follow:

$$F = 1 - \frac{Q_s - Q_{low}}{Q_{high} - Q_{low}} \qquad \text{Eq(1)}$$

where Q_s is the simulation flow. The composite WUA~Q curve can be summarized as follows for the full range of simulation flows:

$$WUA = WUA_{low} \qquad \text{for } Q_s \le Q_{low} \qquad \text{Eq(2)}$$

$$WUA = F \times WUA_{low} + (1 - F) \times WUA_{high} \qquad \text{for } Q_{low} \le Q_s \le Q_{high} \qquad \text{Eq(3)}$$

$$WUA = WUA_{high} \qquad \text{for } Q_s \ge Q_{high} \qquad \text{Eq(4)}$$

Those equations can be applied to calculate the composite WUA curves for transects with more than two calibrated velocity profiles. For example: A transect may have three calibrated velocity profiles from Q_{low}, Q_{mid}, and Q_{high} measurements. The subscript "high" in Eq(1) and Eq(3) should be replaced by "mid" to calculate the WUA for flows between Q_{low} and Q_{mid}. When calculating the WUA for flows between Q_{mid} and Q_{high}, the subscript "low" should be replaced by "mid".

Numerical values of the WUA curves in Figure3 are listed in Table 1. Columns 2 and 3 are the WUA curves for Q_{low} and Q_{high}, respectively. Column 4 is the weighting factor, F, calculated from Eq(1), for each simulation flow. Column 5 is the composite WUA, computed using Eq(3) and it reads Column 5 =F * Column 2 + (1-F)*Column 3.

(C) Application to all PHABSIM transects

The algorithm described previously was applied to calculated composite curves for all species and lifestages of all 117 transects in the four basins. The composite WUA curves are shown in Attachment 2, Supplement 1 for the transects on NFK, SFK, UT, and KR. Also shown on the graphs of each transect are the plots of percentage of maximum WUA, which is the ratio of a WUA value to the maximum value on the WUA curve.

Weighted Usable Area (WUA) curves for spawning anadromous (top) and non-anadromous (bottom) salmonids at Transect 08-SFK1-MS2-TR1 (River Kilometer 19.21) in SFK-A, South Fork Koktuli River, Alaska.

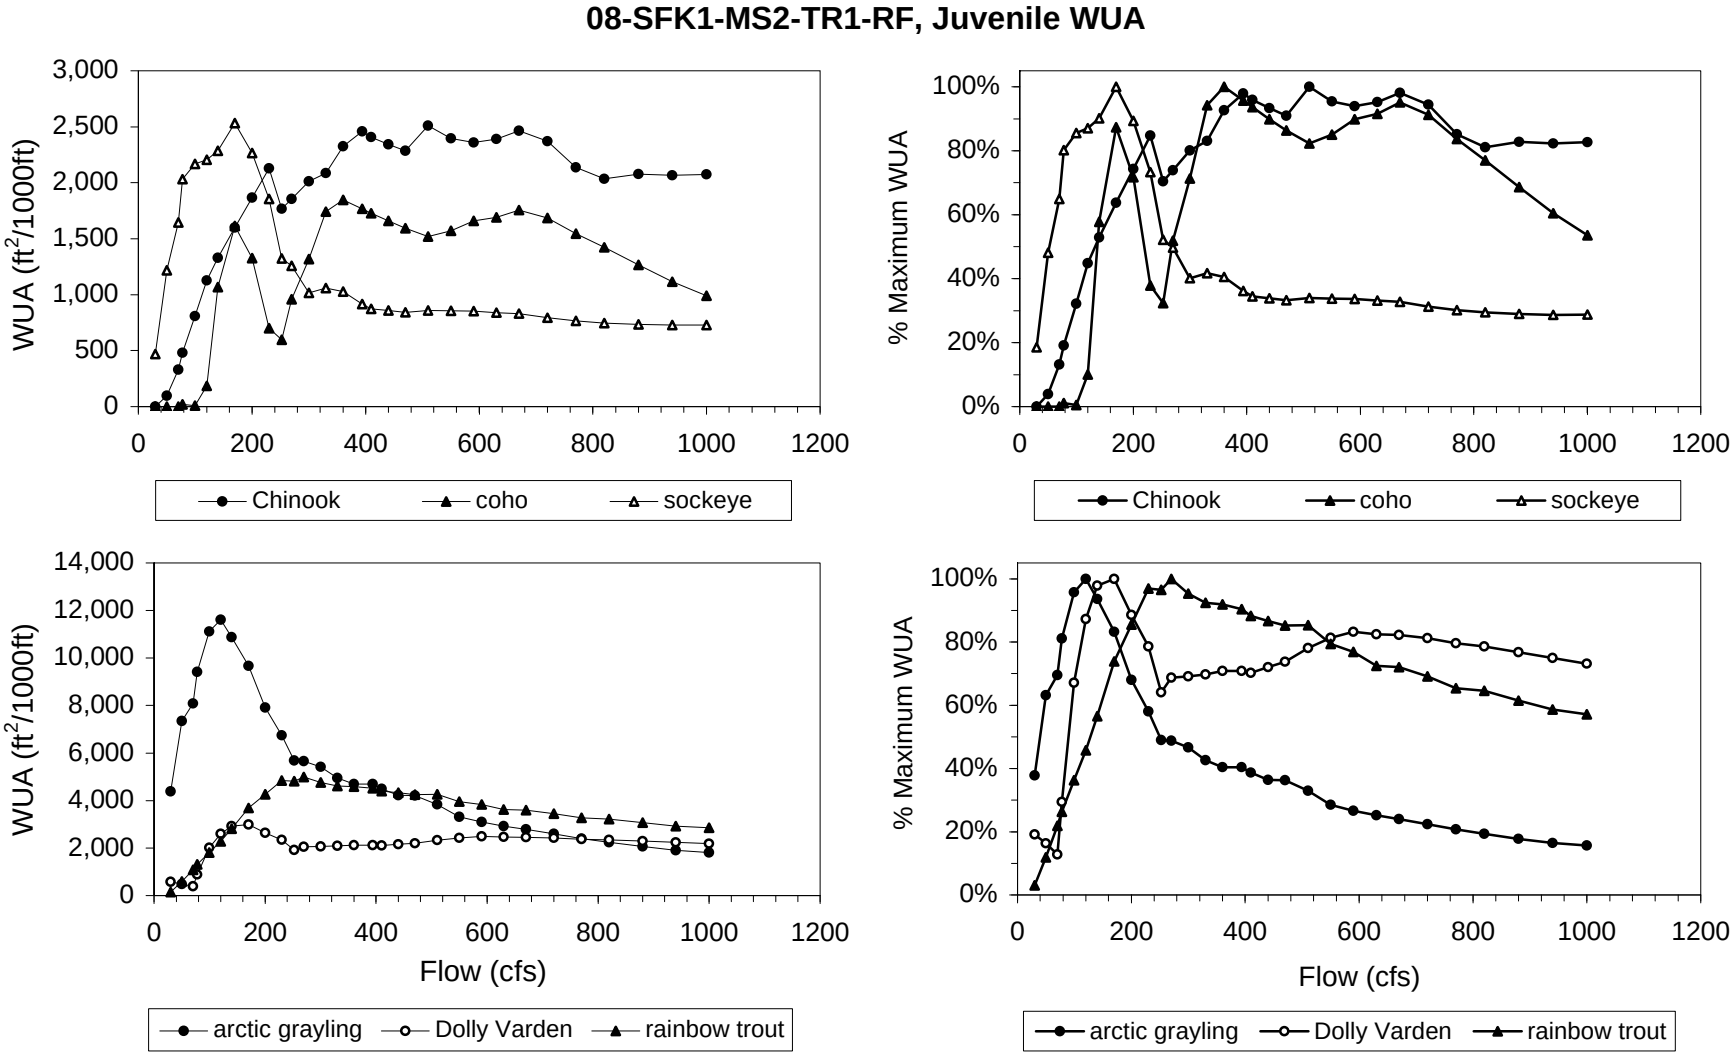

Figure 119
Weighted Usable Area (WUA) curves for juvenile anadromous (top) and non-anadromous (bottom) salmonids at Transect 08-SFK1-MS2-TR1 (River Kilometer 19.21) in SFK-A, South Fork Koktuli River, Alaska.

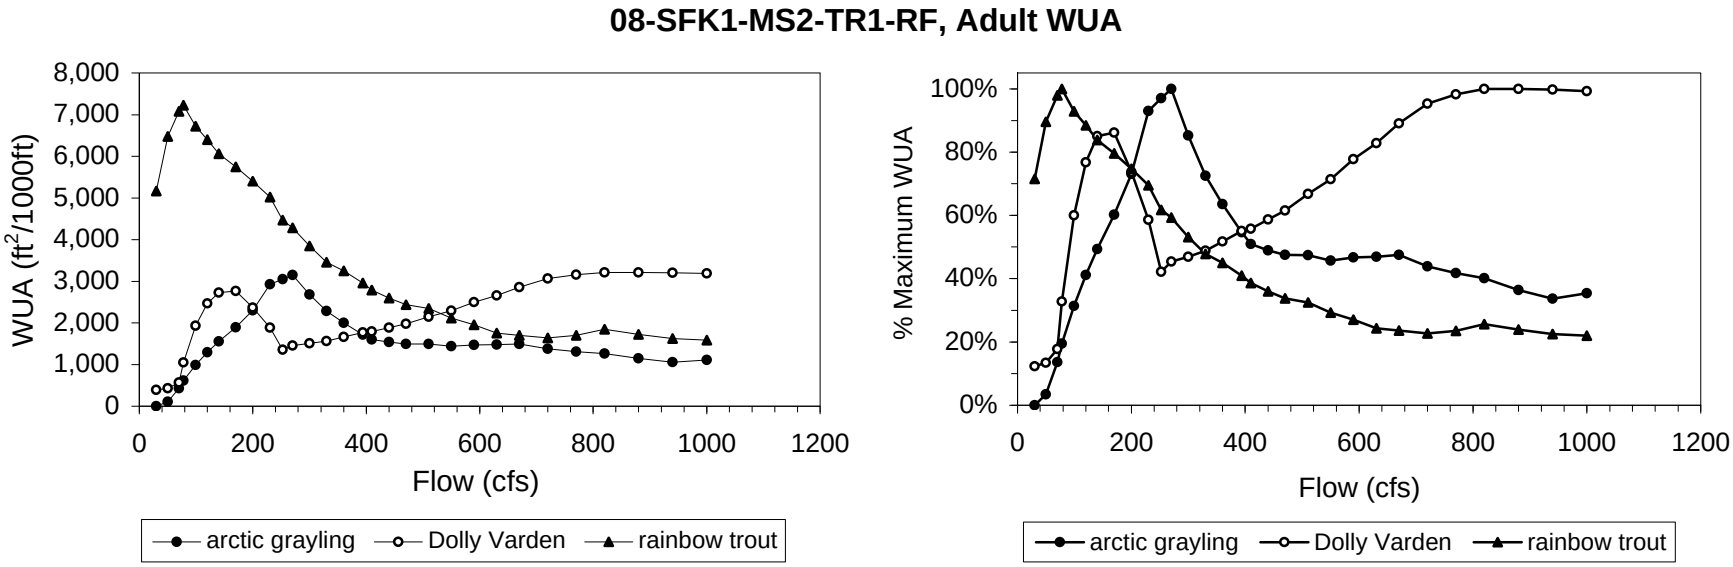

Figure 120
Weighted Usable Area (WUA) curves for adult non-anadromous salmonids at Transect 08-SFK1-MS2-TR1 (River Kilometer 19.21) in SFK-A, South Fork Koktuli River, Alaska.

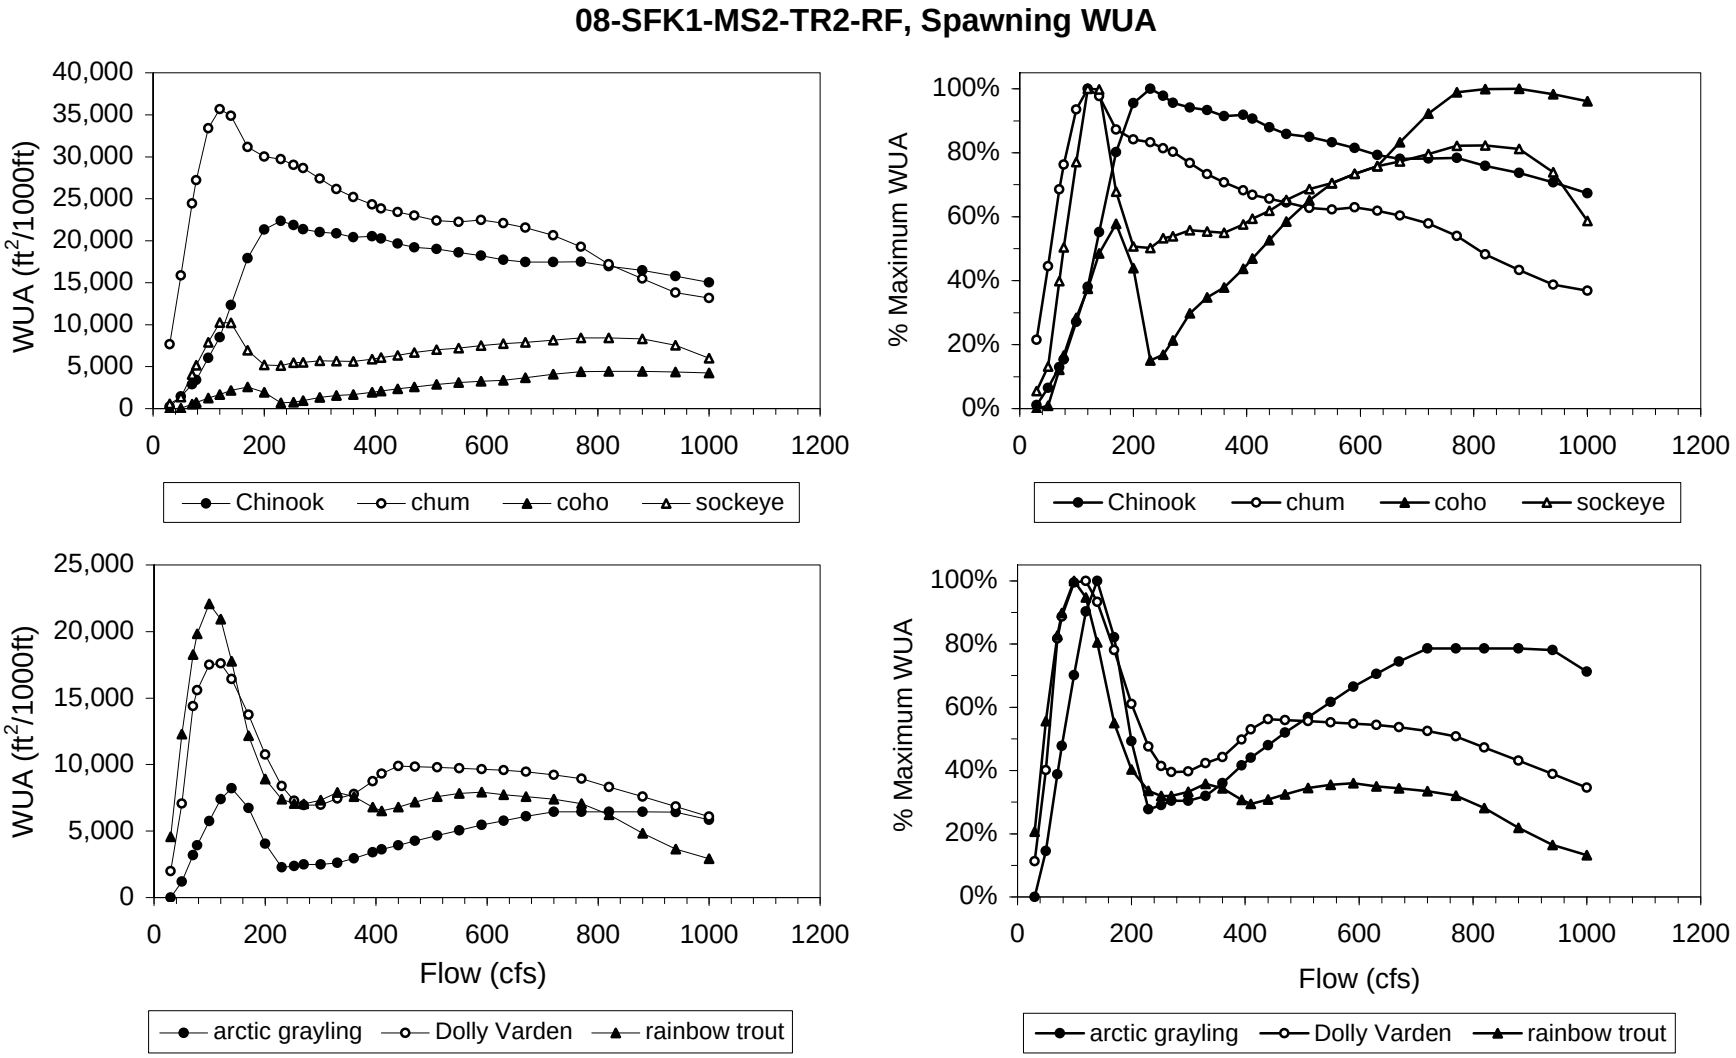

Figure 121
Weighted Usable Area (WUA) curves for spawning anadromous (top) and non-anadromous (bottom) salmonids at Transect 08-SFK1-MS2-TR2 (River Kilometer 19.29) in SFK-A, South Fork Koktuli River, Alaska.

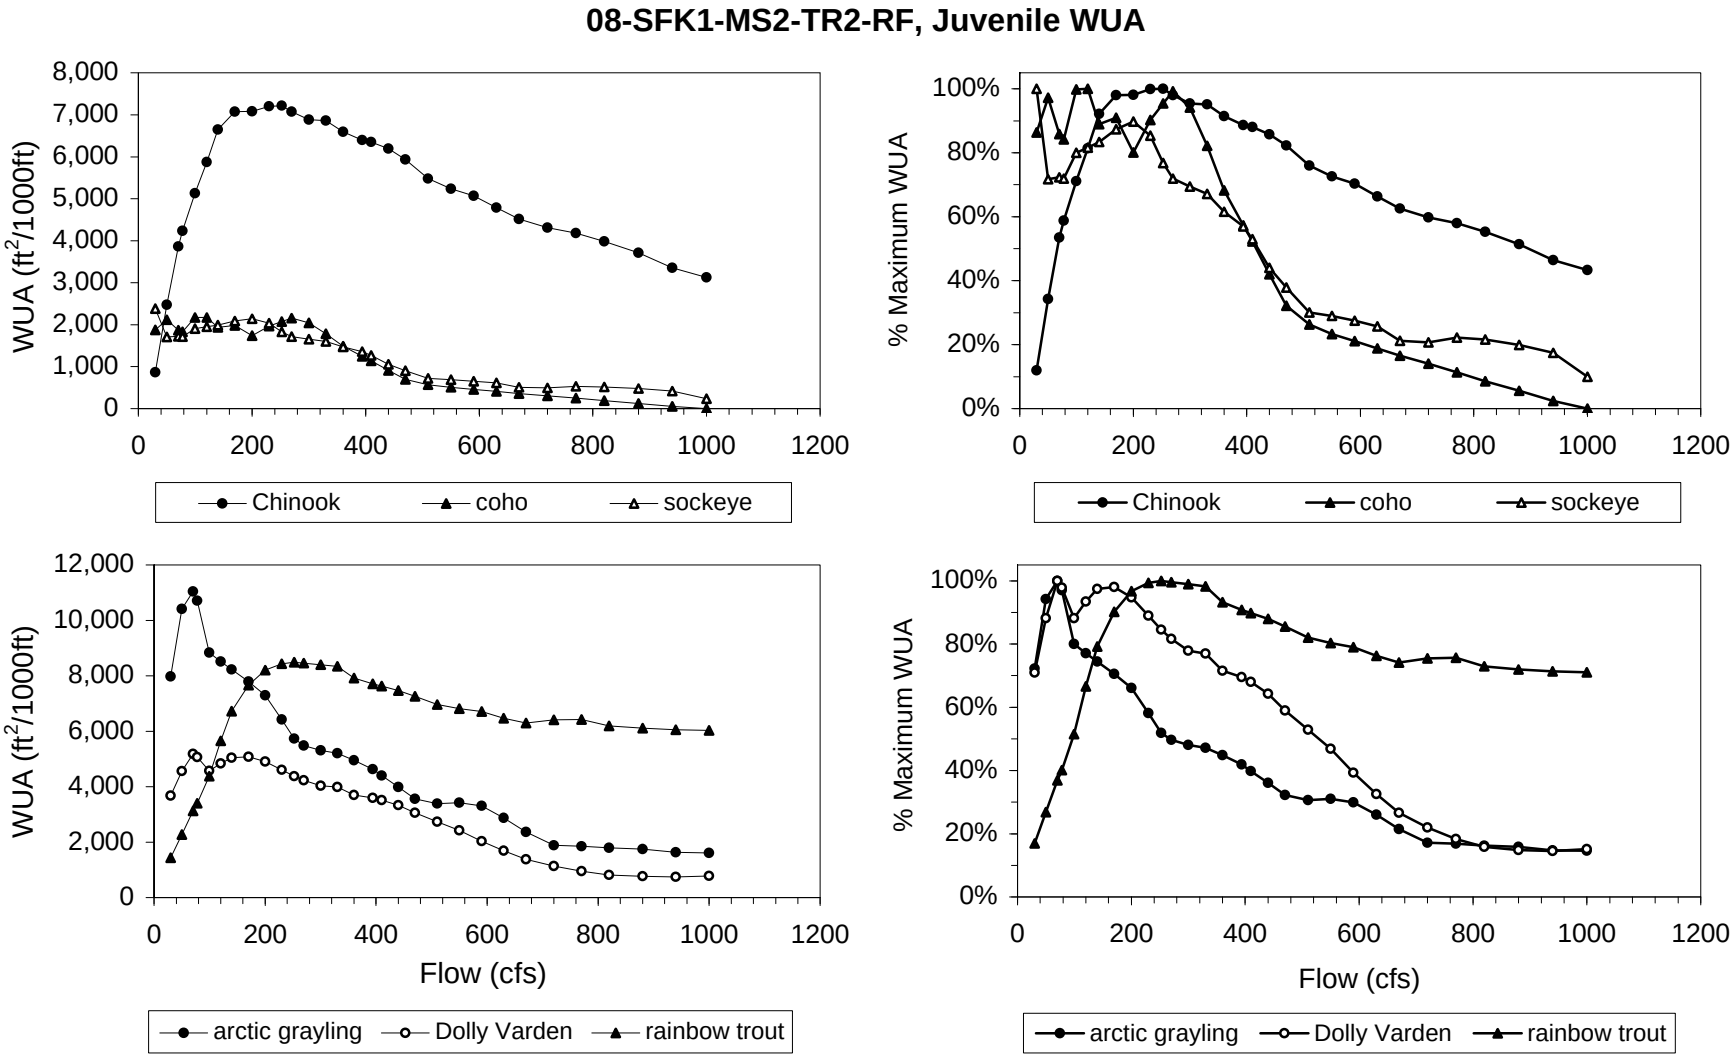

Figure 122
Weighted Usable Area (WUA) curves for juvenile anadromous (top) and non-anadromous (bottom) salmonids at Transect 08-SFK1-MS2-TR2 (River Kilometer 19.29) in SFK-A, South Fork Koktuli River, Alaska.

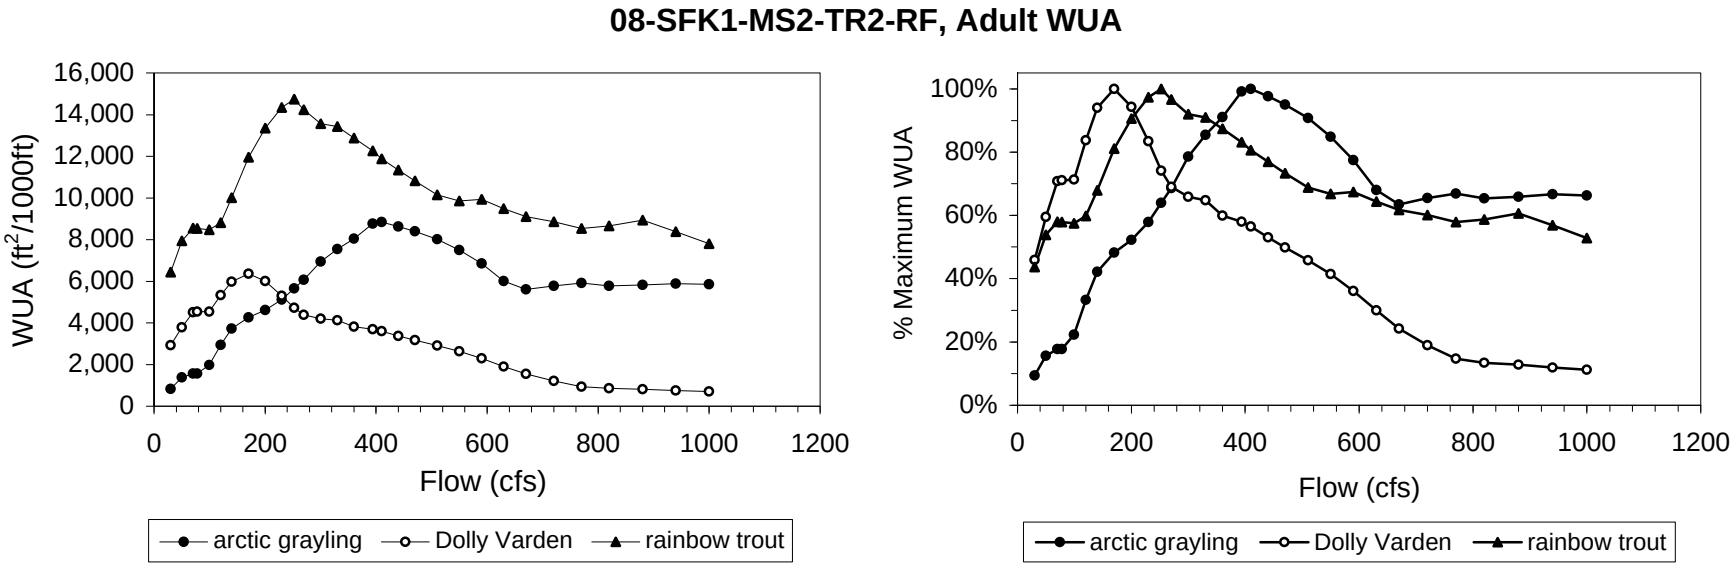

Figure 123
Weighted Usable Area (WUA) curves for adult non-anadromous salmonids at Transect 08-SFK1-MS2-TR2 (River Kilometer 19.29) in SFK-A, South Fork Koktuli River, Alaska.

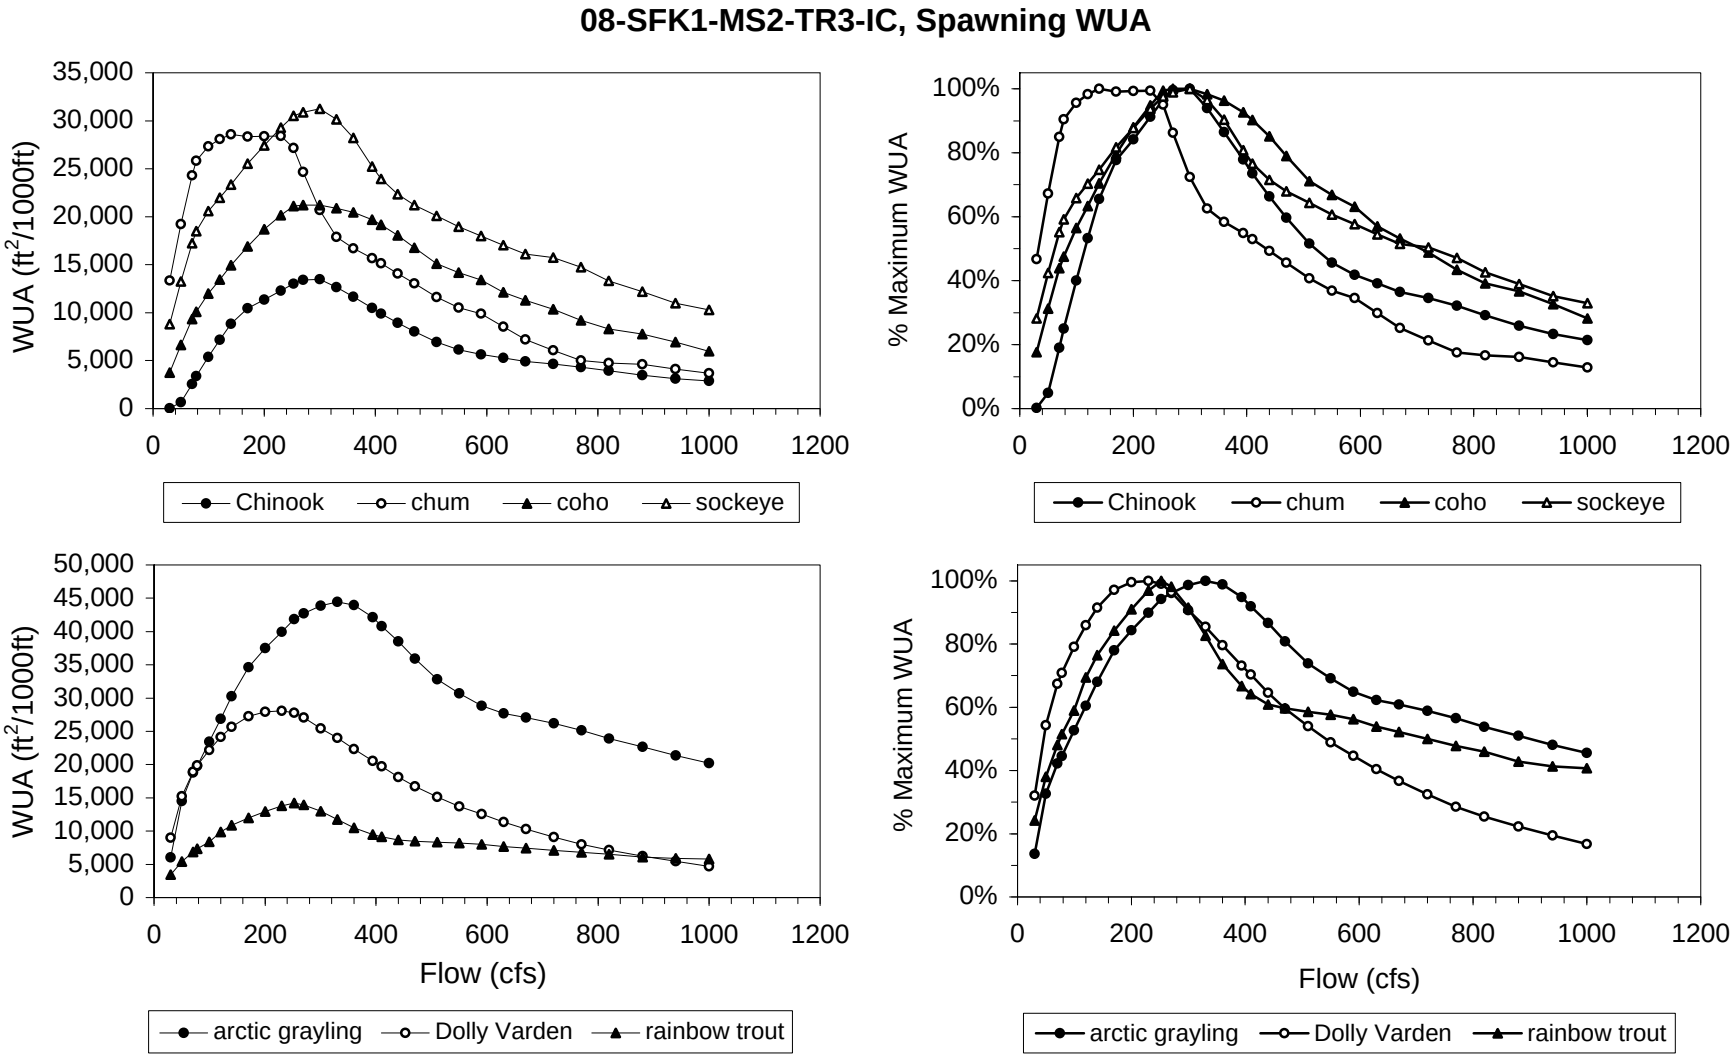

Figure 124
Weighted Usable Area (WUA) curves for spawning anadromous (top) and non-anadromous (bottom) salmonids at Transect 08-SFK1-MS2-TR3 (River Kilometer 19.42) in SFK-A, South Fork Koktuli River, Alaska.

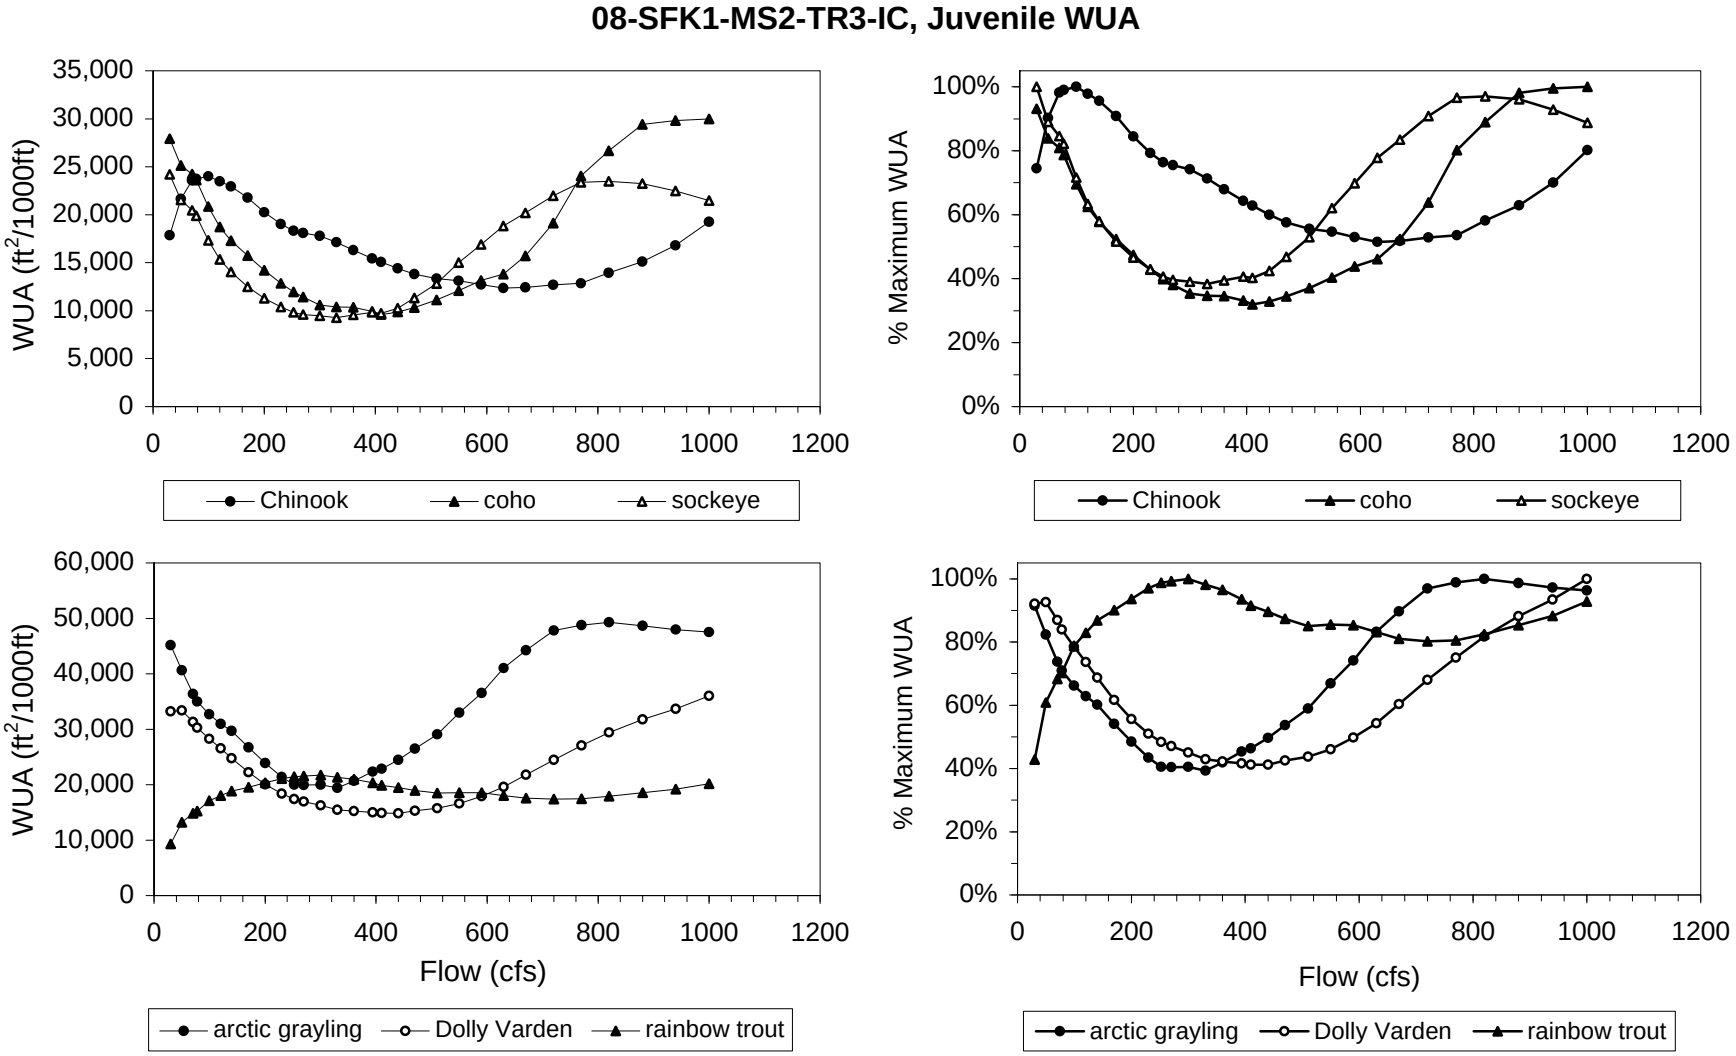

Figure 125
Weighted Usable Area (WUA) curves for juvenile anadromous (top) and non-anadromous (bottom) salmonids at Transect 08-SFK1-MS2-TR3 (River Kilometer 19.42) in SFK-A, South Fork Koktuli River, Alaska.

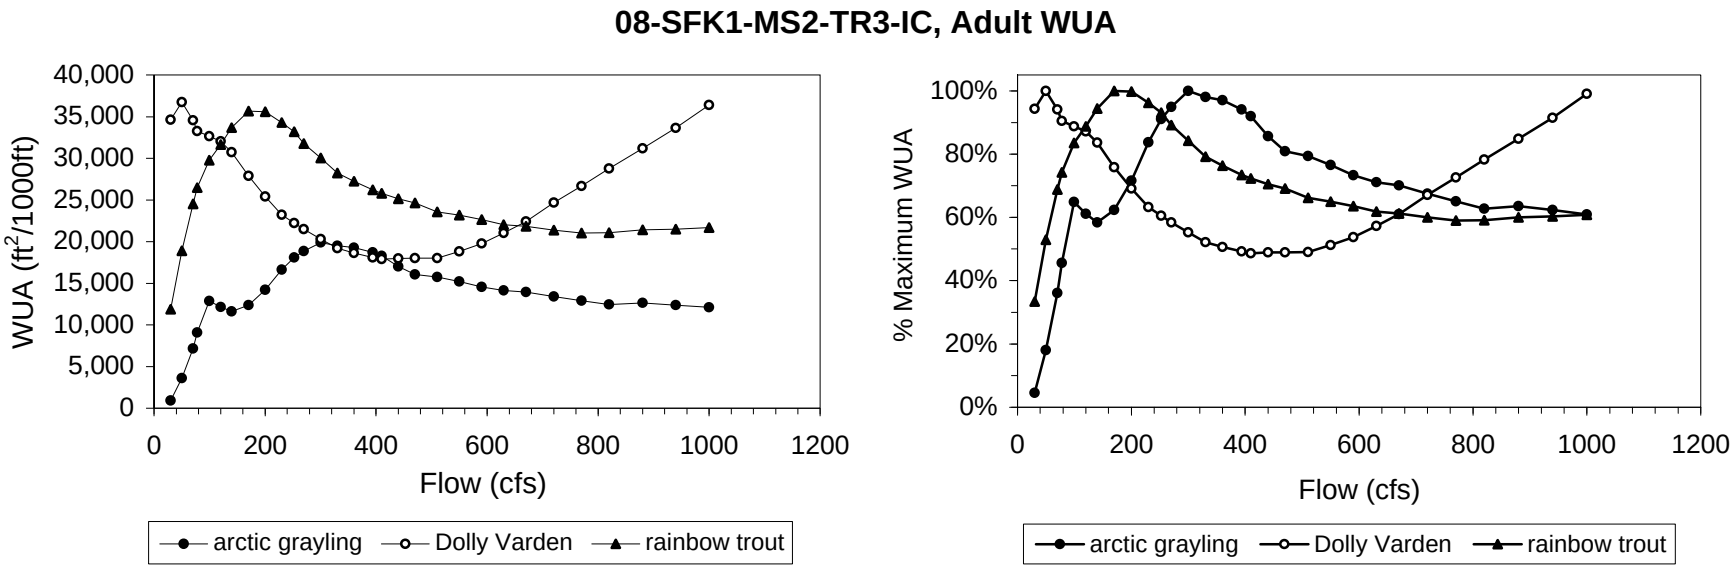

Figure 126
Weighted Usable Area (WUA) curves for adult non-anadromous salmonids at Transect 08-SFK1-MS2-TR3 (River Kilometer 19.42) in SFK-A, South Fork Koktuli River, Alaska.

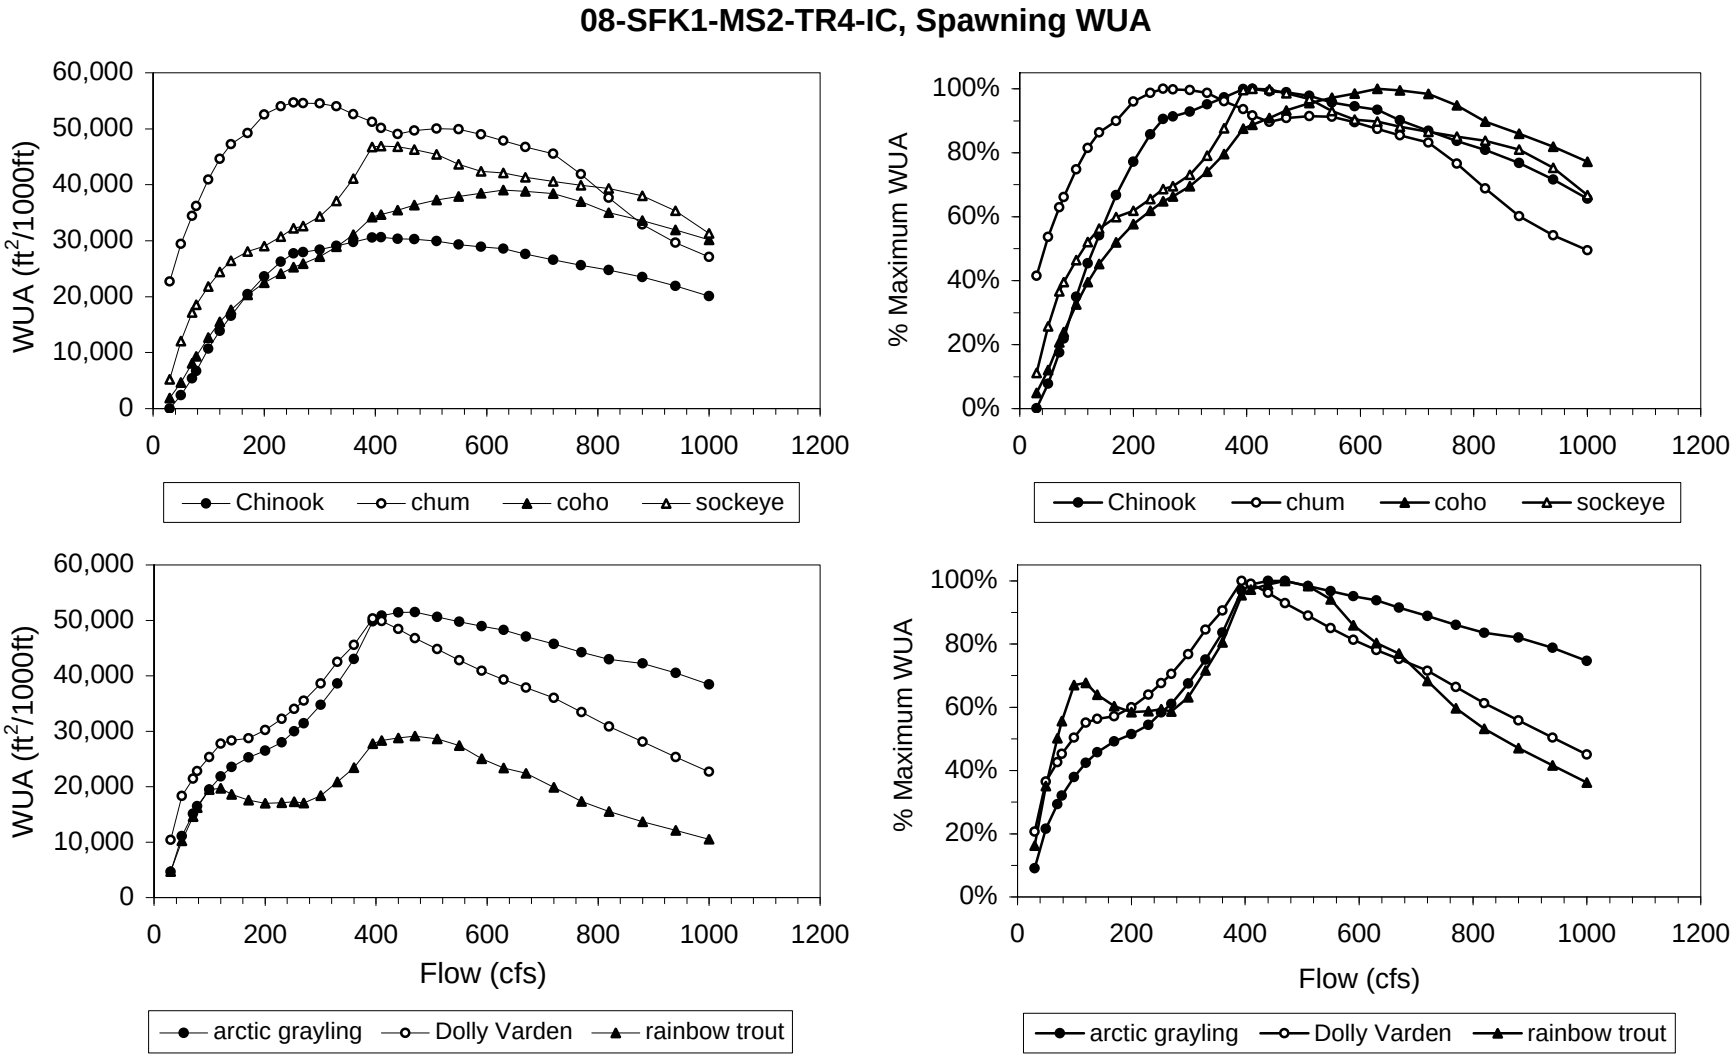

Figure 127
Weighted Usable Area (WUA) curves for spawning anadromous (top) and non-anadromous (bottom) salmonids at Transect 08-SFK1-MS2-TR4 (River Kilometer 19.47) in SFK-A, South Fork Koktuli River, Alaska.

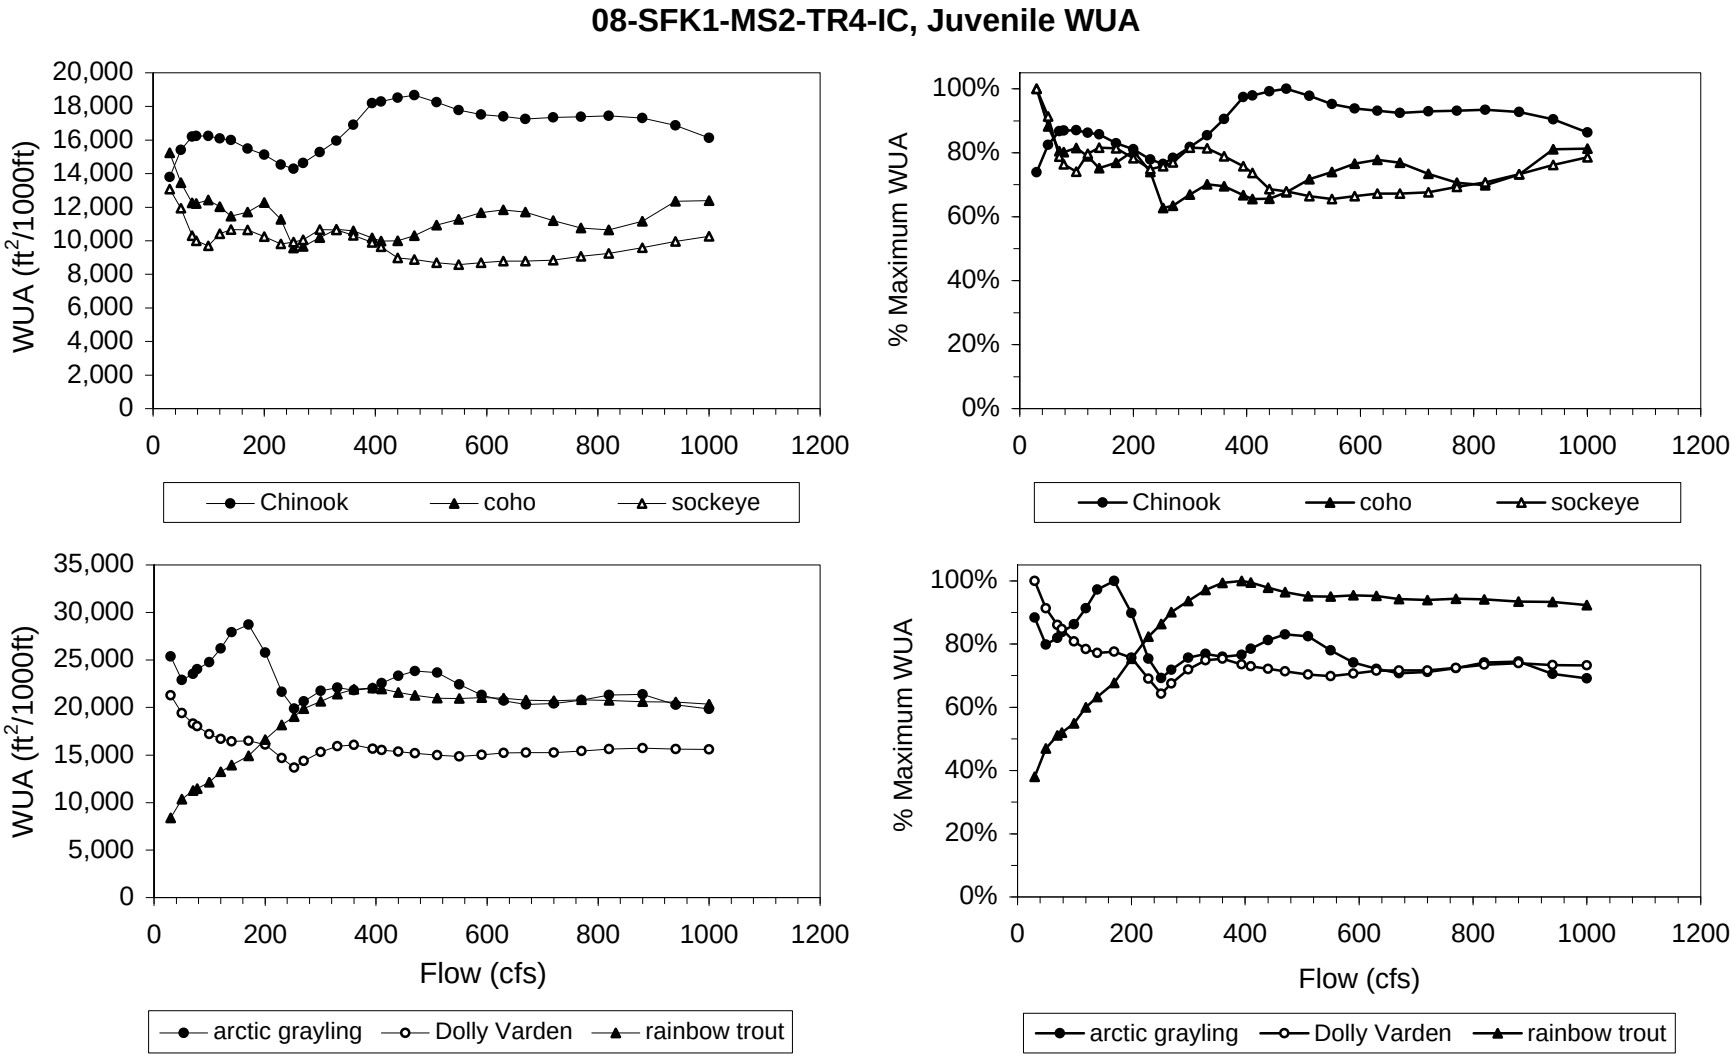

Figure 128
Weighted Usable Area (WUA) curves for juvenile anadromous (top) and non-anadromous (bottom) salmonids at Transect 08-SFK1-MS2-TR4 (River Kilometer 19.47) in SFK-A, South Fork Koktuli River, Alaska.

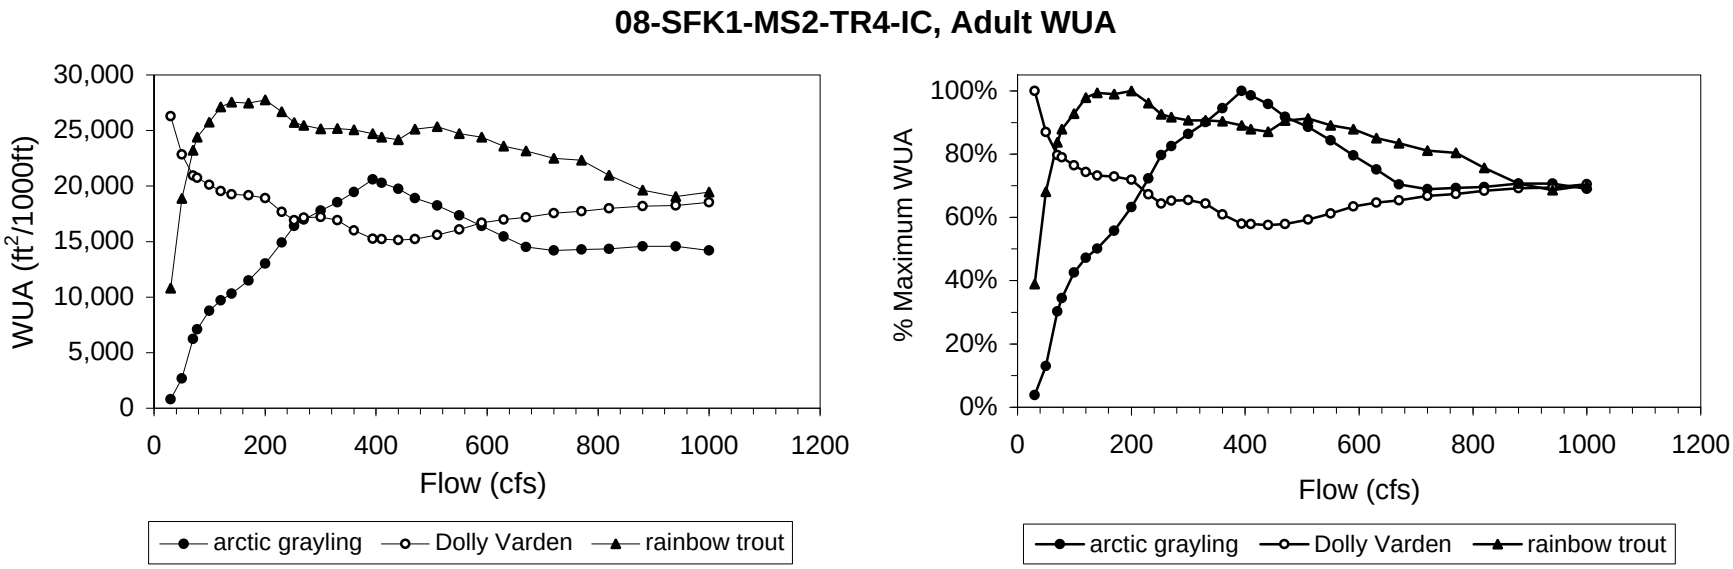

Figure 129
Weighted Usable Area (WUA) curves for adult non-anadromous salmonids at Transect 08-SFK1-MS2-TR4 (River Kilometer 19.47) in SFK-A, South Fork Koktuli River, Alaska.
