   BEGIN STREAM GEOMETRY VERIFICATION OF 'ADDCHG' PROGRAM. THE PURPOSE OF THIS PROGRAM IS TO:
      (1) ADD'M' NODES TO THE STREAM GEOMETRY ('KGNSTRG') FILE WHEN THE ELEVATION BETWEEN THE UPSTREAM & DOWNSTREAM SUBREACH
     NODES WOULD OTHERWISE EXCEED 300 METERS;
      (2) CALCULATE THE AVERAGE LATITUDES & ELEVATIONS FOR THE REACH;
      (3) CALCULATE THE STREAM GRADIENT & STREAMBED TEMPERATURE;
      (4) CREATE THE UNFORMATTED 'KSTRMGM' FILE.
THIS VERIFICATION IS THE FORMATTED VERSION OF 'KSTRMGM'.

********************************** TABLE III: STREAM GEOMETRY AFTER HYDROLOGY NODES MERGED ************************************
   BEGIN STREAM GEOMETRY VERIFICATION OF 'ADDHYD' PROGRAM. THE PURPOSE OF THIS PROGRAM IS TO:
      (1)MERGE THE HYDROLOGY ('D', 'K', 'P', 'Q', 'R', AND 'V') NODES FROM THE HYDROLOGY ('KGNSHDR') FILE WITH THE STREAM
          GEOMETRY ('KSTRMGM') FILE;
      (2) CREATE THE UNFORMATTED 'KSTRMGM' FILE.
THIS VERIFICATION IS THE FORMATTED VERSION OF THE 'KSTRMGM' FILE.

****************************************** TABLE V: HYDROLOGY WITH LATERAL FLOWS ADDED ******************************************
    BEGIN HYDROLOGY VERIFICATION OF 'LATFLO' PROGRAM. THE PURPOSE OF THIS PROGRAM IS:
       (1) COMPUTE LATERAL FLOWS FOR UPSTREAM NODES;
       (2) CREATE THE FINAL UNFORMATTED HYDROLOGY FILE.
 THIS VERIFICATION IS A FORMATTED VERSION OF THE 'KHYDR5' OR 'KHYDROL' FILE.

************************************ TABLE VI: COMPOSITE-STR. GEOM., HYDR., & MET. MERGED ************************************
    BEGIN FINAL HYDROLOGY, STREAM GEOMETRY, ANDLOCAL METEOROLOGY VERIFICATION FOR THE COMPOSITE NETWORK. THE PURPOSE OF
 THIS PROGRAM IS TO:
       (1) GENERATE THE SOLAR DATA;
       (2) GENERATE THE SHADE DATA;
       (3) DETERMINE THE LOCAL METEOROLOGY FOR EACH NODE;
       (4) COMPLETE THE HYDROLOGY DATA AT EACH NON-HYDROLOGY NODE;
       (5) MERGE ALL DATA AT EACH COMPOSITE NODE FOR ALL YEARS AND TIME PERIODS INTO A SINGLE DIRECT-ACCESS FILE.
 THIS VERIFICATION IS A TRUNCATED VERSION CONTAININGTHE NEWLY CREATED DATA FOR 'KMERGE'.

NORMAL COMPLETION OF 'METROL'.

```
****************************************** TABLE VIII: WATER TEMPERATURE DATA ******************************************
    BEGIN INSTREAM WATER TEMPERATURE CALCULATIONS VERIFICATION OF 'NETWRK' PROGRAM. THE PURPOSE OF THIS PROGRAM IS TO:
       (1) DETERMINE THE PREDICTED WATER TEMPERATURE FOR EACH YEAR & TIME PERIOD AT EVERY NODE IN THE COMPOSITE NETWORK;
       (2) GENERATE THE VERIFICATION TABLE;
       (3) GENERATE THE UNFORMATTED OUTPUT FILE FOR THE OUTPUT REPORT GENERATOR AND/OR LINKAGE TO OTHER PROGRAMS.
 THIS VERIFICATION IS THE FORMATTED VERSION OF 'KTRNSPT' FILE.

5. Scope of Work 2
6. Methods 3
6.1 Review and Analysis of Existing Data Sources and Publications 4
6.1.1 Digital Elevation Model 4
6.1.2 Aerial Photograph Interpretation 4
6.1.3 Hydrologic Data 4
6.2 Channel Geometry and Hydraulic Modeling 6
6.2.1 Fluvial Geomorphology Site Selection 6
6.2.2 Field Data Collection 7
6.2.2.1 Temporary Benchmark Establishment and GPS Locations 8
6.2.2.2 Reference Reach Cross-Sections 8
6.2.2.3 Downstream Hydraulic Model Boundary Cross-Section 8
6.2.2.4 Vegetation Lines 9
6.2.2.5 Tops of Banks 9
6.2.2.6 Longitudinal Profiles 9
6.2.2.7 Stage-Discharge Data 9
6.2.2.8 Pebble Count 9
6.2.3 Remote Sensing Analysis 9
6.2.4 Hydraulic Modeling 10
6.2.4.1 Field Data Reduction 10
6.2.4.2 HEC-RAS Model Development 10
6.2.4.3 HEC-RAS Model Flows 11

6.2.4.4 HEC-RAS Model Calibration and Simulation 11
6.2.5 Development of Hydraulic Geometry Relationships 11
6.2.6 Tributary Habitat Data 13
6.3 Particle Mobility Study 13
6.3.1 Study Site 14
6.3.2 Radio Rock Preparation and Deployment 14
6.3.3 Data Recording and Analysis 15
6.4 Fine Sediment Levels in Spawning Gravels 17
6.4.1 Spawning Gravel Study Sites 17
6.4.2 Field Data 17
6.4.2.1 Sample Size 18
6.4.2.2 Sediment Sampling 18
6.4.2.3 Sieving and Data Analysis 19
6.4.2.4 Specific Gravity and Gravel Source Lithology 20
7. Results and Discussion 20
7.1 Geomorphic Variation Within and Between Mainstem Rivers 21
7.1.1 Physiographic and Planform Features 21
7.1.2 Reach Scale Hydraulic Geometry and Sediment Characteristics 22
7.1.3 Ice Processes 23
7.1.3.1 Variation in Ice Processes Across Spatial Scales 23
7.1.3.2 Influences of Ice Processes on Fish and Riparian Habitats 25
7.1.4 Beaver Activity 25
7.1.4.1 Variation in Beaver Dam Location Across Spatial Scales 25
7.1.4.2 Influences of Beaver Activity on Fish and Riparian Habitats 26
7.1.5 Sediment Sources 26
7.1.5.1 Tributary Sediment Source Characteristics 27
7.1.5.2 Mass-Wasting and Bank Erosion 27
7.2 Channel Geometry and Hydraulic Modeling 27
7.2.1 Channel Forming Flow Regressions Classified by Basin 28
7.2.2 Channel Forming Flow Regressions Classified by Channel Slope 28
7.2.3 Channel Geometry Relative to Alternative Hydrologic Metrics 30
7.3 Particle Mobility Study 30
7.4 Fine Sediment Levels in Spawning Gravel 31
8. Summary 31
9. References 32

FLUVIAL GEOMORPHOLOGY STUDIES

1. INTRODUCTION

Fluvial geomorphology is the study of river form and the physical and biological conditions and processes influencing channel morphology. Channel morphology can be characterized in terms of numerous parameters, including: measures of channel geometry (width, depth, and slope), cross-section shape, riverbed grain size distribution, planform shape, channel conveyance, sediment transport capacity, and measures of the ways in which each of these features may change. Fundamental conditions and processes influencing channel morphology, and the ways in which it may change, include: the underlying local and upstream geology, hydrology, hydraulics, sediment supply, sediment transport, and biophysical influences. In turn, these various characteristics of channel form and function influence the quantity and quality of aquatic and terrestrial habitat for plants and animals that depend on the river environment for all or part of their life history. For example, habitat availability at different stream flows will reflect channel size and form and their influences on hydraulic conditions, as represented in the Instream Flow: Main Channel Habitat Study (IF Study; Appendix 15.1E). Accordingly, this Fluvial Geomorphology Study (study) was conceived in large part to be linked with the IF Study results, to provide a means for linking predicted changes in hydrology and drainage area with changes in fish and aquatic habitat. This study is also intended to characterize general fluvial geomorphic conditions in the study area.

This appendix describes the current channel conditions and processes influencing channel morphology in the Pebble Project fluvial geomorphology study area, with a particular emphasis on the features that influence aquatic and riparian habitat quantity and quality.

2. STUDY OBJECTIVES

The goal of this study is to describe, as completely and concisely as possible, dominant fluvial geomorphic conditions and processes found in the study area. Channel morphologic variations are defined based on large-scale physical characteristics influencing channel form, and in terms of site-specific channel characteristics. Physical controls on local channel form and processes are also described. Emphasis is placed on describing channel characteristics that are most likely to be affected by changes in hydrology and sediment supply associated with the Pebble Project, and providing the underlying basis for subsequent assessments of potential effects to channels and aquatic habitat. This study is, thus, closely linked with the IF Study where habitat quantity is controlled in part by channel size and form.

3. STUDY AREA

The fluvial geomorphology study area is defined here as the region bounded and drained by the mainstem channels of three rivers: the North Fork Koktuli River (NFK), the South Fork Koktuli River (SFK), and Upper Talarik Creek (UT; Figure 1). This is the area within which the Pebble Deposit is located. The NFK and SFK merge to form the Koktuli River. Most fluvial geomorphology data have been collected in

the three main river channels, with limited data also collected in selected tributaries draining to each mainstem from primarily the bounded area, and in one site in the Koktuli River below the confluence of the two forks. More detailed information has been developed for channels within the Pebble Deposit area than in outlying areas.

4. PREVIOUS STUDIES

The fluvial geomorphology of the study area does not appear to have been previously studied. An assessment of streams draining into Bristol Bay presented only large scale geology maps (TNC, 2004). This study represents the first detailed assessment of channel form and process in the study area. In addition, information is compiled from studies of geomorphic processes that have been conducted in other Alaska and northern clime streams and, more generally, in gravel bed rivers. These studies have results that are generally applicable to describing geomorphic processes in the study area. Such studies are referred to, as necessary, in Section 7 below.

5. SCOPE OF WORK

A combination of field studies and comparative literature-based evaluation was used to characterize fluvial geomorphology in the study area. Fluvial geomorphology field surveys were conducted in 2005, 2007, and 2008. Field studies were conducted by HDR Alaska, Inc. (HDR) and Inter-Fluve Inc. (IFI) in 2005 and 2007, and by R2 Resource Consultants, Inc. (R2) with assistance from HDR in 2008. Pacific Hydrologic Inc. provided technical support and review capacity over the course of the study. Results presented in this document are based on the review of relevant studies and literature from other similar streams to generally evaluate key geomorphic processes, and from the analysis of data collected from 2004-2008 in the context of this information.

In the summer of 2005, IFI was contracted by HDR to initiate a pilot fluvial geomorphology study. Field work was conducted in the SFK and UT, and focused on describing channel geometry relationships and hydraulic modeling. The data were analyzed and evaluated to determine whether the general approach and data collected could be used to assess channel responses to changes in discharge, primarily in support of the IF Study. The results from the 2005 pilot study suggested more mobile riverbed conditions were present than expected based on published research. The analysis of the 2005 data also suggested that simple hydraulic approximations of stage-discharge relationships could not be applied to accurately model hydraulic conditions influencing channel stability and sediment transport. Therefore, additional field data were needed from more sites to better describe the relation between channel geometry and geomorphic processes.

Work was reinitiated in 2007 and expanded on the 2005 channel geometry and hydraulic modeling by including the addition of field data from the NFK and re-sampling of the 2005 fluvial geomorphology study sites (FG sites). The objective of the 2007 field work was to collect more information that could be used for better establishing relationships between stream channel geometry and stream hydrology in the study area. These relationships were intended to support the IF Study and to describe baseline conditions. The effort involved measuring and assessing channel geometry dimensions and identifying a characteristic discharge approximating bankfull flow conditions (Leopold and Maddock, 1953). The bankfull discharge is a representative flow parameter that has been related to hydrologic and hydraulic

conditions influencing channel form, primarily in alluvial channels, and may be used under certain circumstances to relate changes. The 2007 work also included collecting single gravel samples from FG sites to begin assessing fine sediment levels in the river bed substrates as part of a pilot study. Those data were inconclusive, leading to subsequent replicate sampling in spawning gravels (Section 6.4). In 2007, a radio rock study was also conducted to evaluate riverbed mobility in more detail. The particle mobility study focused on a single site in the NFK.

In 2008, single gravel samples were collected in additional FG sites to add to the pilot study data set, and in new sites containing spawning habitat. Replicate gravel samples were also collected in sites with spawning habitat to:

- Statistically assess pre- and post-spawning fine sediment levels.
- Address the question of how the particle size distribution in known salmon spawning locations is affected by fall high flow events and subsequent resorting of bed materials.

6. METHODS

The fluvial geomorphology study results are used to describe important channel processes and characteristics over a range of scales, from basin-wide variation down to site-specific features. There is, necessarily, some overlap in the presentation of methods in this section, where results from a specific study element can be applied at both basin-wide and site specific scales, particularly in the case of field sites. The primary sources of relevant information and data collected and assessed included:

- Published geologic and United States Geological Survey (USGS) topographic maps of the study area.
- Literature pertinent to important geomorphic processes occurring in the study area rivers, supplemented with field-based visual observations where appropriate.
- Geographic information system (GIS) analysis of a Digital Elevation Model (DEM).
- GIS analysis of georeferenced aerial photographs taken in 2004.
- Field data collected at forty-nine (49) mainstem river and three (3) tributary sites for detailed hydraulic modeling and channel size analysis, with sites located to describe basin-wide variation in site-specific geomorphic and hydraulic geometry characteristics.
- Hydrology data used to assess geomorphically effective flows at the field sites.
- Field data collected in selected tributaries to describe general aquatic habitat and channel size characteristics that are also relevant to describing general geomorphic conditions.
- A detailed field study of particle mobility in the NFK.
- A detailed field study of fine sediment levels in spawning gravel at three (3) sites in each mainstem river channel for a total of nine (9) sites.

Methods employed for each of these study elements are described in greater detail below. In general, basin-wide characterizations focus on upstream-downstream variation in characteristics across field sites, whereas site-specific characterizations focus primarily on site-scale conditions and processes.

6.1 REVIEW AND ANALYSIS OF EXISTING DATA SOURCES AND PUBLICATIONS

Available published information specific to the study area was limited and consisted primarily of geologic mapping. Geologic maps of surface units by Detterman and Reed (1973) provide information on the underlying geology and geologic history of the study area. These data were supplemented by more detailed mapping of the area surrounding the Pebble Deposit prepared by Hamilton (2007).

Geophysical and aquatic science literature databases were searched for published work relevant to fluvial geomorphic processes in similar river systems in the southwest region or State of Alaska, in northern climes, and in gravel bed rivers in general. Emphasis was placed on identifying peer-reviewed papers and summary treatises describing: 1) development of hydraulic geometry relations and 2) the inter-relationships between ice processes and beaver activity with channel form and function, and with fish habitat. Papers focusing on hydraulic geometry were compared against results derived from the field studies described below.

The following sources of information and data used in fluvial geomorphology analyses were developed specifically in support of the Pebble Project.

6.1.1 DIGITAL ELEVATION MODEL

A DEM was created for the Pebble Project by Eagle Mapping Inc. from 2004 orthophotos. The Pebble DEM was used to create longitudinal distance-elevation profiles of each mainstem river channel, determine sinuosity (ratio of channel length to valley length), and measure valley widths to support an assessment of channel confinement (valley width/channel width). The DEM was also used in conjunction with USGS topographic maps to derive drainage area for sites of interest.

6.1.2 AERIAL PHOTOGRAPH INTERPRETATION

Aerial photographs were used in conjunction with site photographs and the DEM to derive channel confinement (valley width/channel width) and sinuosity (river channel length/valley length) data for each mainstem FG site. The bankfull width estimates from the FG sites were used in calculating the confinement ratio, where valley width was set equal to visible floodplain extent using the aerial photographs and DEM contour lines as guides in GIS. The valley length evaluated for sinuosity was set to 500 meters up-valley and 500 meters down-valley of each FG site, and the corresponding length of river was calculated from perpendicularly clipped stream segments in GIS.

6.1.3 HYDROLOGIC DATA

Hydrologic data were evaluated for the study area in conjunction with channel geometry data (Section 6.2) to provide a framework for establishing quantitative linkages between project effects on stream flow, channel size, and fish habitat availability. In essence, if channel form reflects hydrology, changes in the stream flow regime will result in changes in channel hydraulic geometry parameters such as bankfull depth and width. These parameters, in turn, are related to fish habitat quantity. Functionally, channel bankfull geometry may be correlated with bankfull flow magnitude, which in turn may be correlated with hydrologic metrics. Because estimating bankfull flow magnitude involves extensive, site-specific data

collection, use of a more readily estimated surrogate hydrologic flow parameter would permit more extensive assessment of project hydrologic effects. The problem thus becomes identifying a suitable hydrologic flow parameter that is either indirectly correlated with bankfull channel geometry characteristics through a bankfull or channel forming discharge estimate, or is directly correlated thus obviating the need to accurately estimate bankfull flow itself.

Accordingly, Knight-Piesold, Ltd. used available gaging data to estimate the 5 percent and 1 percent exceedence flow levels and the 2-year and 10-year flood event peak flows for fluvial geomorphology sites where channel forming flow and bankfull width and depth estimates were developed. These combined flow magnitudes represent a range of sediment transporting flows that may influence channel morphology. Stream flow statistics were estimated for most sites by scaling values from the Pebble gaging station network. Flow statistics were not estimated for FG sites located in the lower reaches of UT below Gaging Station UT100B, because of the short periods of record at gaging stations located in the lower watershed.

The daily discharge exceedence analysis was based on station records encompassing the 4 water years from October 1, 2004, through September 30, 2008. The period of record of available data appears to be reasonable for estimating the higher frequency flow statistics. The record is, however, relatively short for other parameters. Therefore, the longest recurrence interval parameter evaluated, the 10-year flood flow estimate, has the greatest uncertainty of the hydrologic statistics evaluated. The records for some stations were extended by regression analysis to cover the complete 4-year period.

Flow duration curves were developed for each station and the 1 and 5 percent exceedence values were extracted. Peak flow estimates were derived from previous analyses for each gaging station using a combined local and regional approach, as described in Appendix 7.1C of the Environmental Baseline Document (EDB, December 2008). Local gage records were used to estimate the 2-year peak flow values at each station, and regional scaling factors were applied to derive peak flow magnitudes for longer return periods.

The peak flow analysis presented in the EBD found that peak flows along the mainstem channels generally scaled by the ratio of drainage areas raised to the power of 0.97, or close to 1. This means that flood intensity (peak discharge per unit area) is roughly proportional to drainage area in the study area. This result appears to reflect the relatively uniform snowmelt and frontal precipitation inputs that generate floods in this area, as well as the relatively long time for water to flow through the basin due to thick surficial materials, thick tundra vegetation, and abundant pond storage over much of the landscape. However, steeper upland tributary basins generated distinctly higher flood intensities that were scaled by the ratio of drainage areas raised to the power of 0.80. The higher unit discharge values and the different scaling behavior in the upland tributary basins appear to reflect shorter times of concentration associated with near-surface bedrock, thin vegetation, and lack of storage features.

Most of the FG sites are situated along mainstem channels between gaging stations. The estimated 1 and 5 percent exceedence values and the 2-year and 10-year peak flows were interpolated from gaging station values by prorating the drainage area. For FG sites on tributaries, the exceedence and peak flow estimates were scaled by prorated drainage area from the most representative gaged basin, including either gaged tributaries or incremental basins between two gaging stations. Peak flows were scaled by the ratio of drainage areas raised to the power of 0.8 or 1.0 for steep, upland tributaries or flat, lowland tributaries, respectively, as supported by the peak flow analysis in the EBD.

6.2 CHANNEL GEOMETRY AND HYDRAULIC MODELING

The three major rivers in the study area are primarily single-thread, alluvial gravel bed channels. The rivers, therefore, have distinct channel and floodplain profiles such that flows spill from the channel onto the floodplain at a defined 'bankfull' flow (Parker et al., 2007). There is evidence of underfit channels in the study area, reflecting valleys formed by meltwater runoff during glaciation (Hamilton, 2007).The existing mainstem channels, however, appear to have evolved since glaciation into an alluvial morphology that reflects the geologically recent, post-glacial flow regime. Given this, the bankfull flow in alluvial channels can be used as an approximation of a characteristic geomorphically effective, 'channel forming' flow. This flow represents an integration of the effects of the range of flows transporting sediments and influencing the channel boundary shape and dimensions. The channel-forming flow is lower in magnitude than occurs during extreme runoff events, but it occurs frequently enough that it tends to transport the greatest sediment volume over time (Leopold and Maddock, 1953; Wolman and Miller, 1960; Williams, 1978; Copeland et al., 2000). In practice, the channel-forming flow estimate is correlated with the shape and physical dimensions of the river channel.

General relationships may be established between measures of channel size and geomorphically effective discharge(s) that exhibit a degree of similarity across spatial scales (Leopold and Maddock, 1953; Castro and Jackson, 2001; Pitlick and Cress, 2002). Overall, such relationships can exhibit variability for a given channel dimension and flow rate, reflecting differences in bank strength, channel flow resistance, and gravel supply. General trends, however, appear to remain consistent across different channel types and regions (Parker et al., 2007; Wohl and David, 2008).

Hydraulic geometry relationships may be used to scale up and down across basin size and flow rates. This may provide a tool for assessing potential effects of changes in hydrology and sediment supply on future channel instream conditions. In turn, such predictions may be linked to changes in aquatic habitat quantity, a primary focus of the IF Study. Where possible, basin-specific relations are most appropriate for extrapolating from present to future conditions.

With this in mind, the study was designed to collect appropriate hydraulic geometry data from the three major rivers in the study area. Data included various measures of channel cross-section dimension, as determined by hydraulic modeling and characterization of riverbed surface grain size distribution via pebble counts.

6.2.1 FLUVIAL GEOMORPHOLOGY SITE SELECTION

Detailed data were collected at 52 FG sites: 49 on the mainstem rivers and three on tributaries (Figure 2). Of the 49 mainstem sites, 15 were on the North Fork Koktuli, 16 on the South Fork Koktuli, 1 on the Koktuli River below the confluence of the forks, and 17 were on UT. Two of the three tributary sites were in the SFK drainage and the third was in the NFK drainage.

The FG sites were selected to reflect basin-wide variation in channel (hydraulics), flow (hydrology), and sediment (geology and grain size) conditions in fish producing river segments. Site selection included consideration of sites used in the IF Study or that were associated with active flow gages. Sites were selected within single-thread riffle (or glide) channel segments, with the assumption made that split channel dimensions should reflect single channel dimensions. Channel segments with closed or aggraded

secondary channel inlets and dense floodplain vegetation were also considered acceptable, based on the observation that high hydraulic roughness created by riparian vegetation results in most bankfull flow being concentrated in the main channel.

Areas with strong localized beaver dam influences were avoided because of varied backwater and sediment trapping effects; however, many sections of the river support active beaver colonies and to some extent are affected by beaver activity. Channel segments with bedrock boundaries were also avoided because they were geologically controlled and have different magnitude channel geometry relationships from alluvial channels (e.g., Wohl and David, 2008). Such sites exist, but are generally uncommon within the study area.

Candidate sites were identified on maps and aerial photographs and then reviewed in the field during helicopter flyovers and/or by landing and walking the area. Once a site was considered suitable by IFI and HDR personnel, its location was marked by a waypoint on a handheld global positioning system (GPS) unit.

The specific site location was selected in the field by three IFI/HDR staff to generally include a single riffle serving as a "reference reach." In a few cases, other channel type units with approximately uniform flow conditions were chosen to be the reference reach where well-defined riffles did not exist, did not meet the site selection criteria for being single-threaded with alluvial banks, or were not considered suitable based on field evaluation of flow conditions. Transects were placed:

- Across the reference reach.
- At a downstream boundary cross-section that provided a degree of hydraulic control upstream; transects were typically placed at the crest of the first pool tailout or riffle downstream of the reference cross-section used to define channel forming flow.
- At intervening channel locations describing changes in channel width and depth for hydraulic modeling purposes.

There were a few exceptions in sites located within reaches lacking extensive, distinct pool-riffle sequences. For example, the upper SFK consisted mostly of pools separated by pool crests. In these situations, field personnel selected a pool crest in which the substrate and geometry were judged to best represent the rest of the reach for a pebble count. The site survey would generally extend a few channel units upstream and downstream, capturing all locations where stream-wise water surface slope changed. Sites that lacked any bedforms (FGSK11, FGSK12, and FGNK12 – Figure 2) had transects placed far enough apart for a normal depth approximation.

Table 1 lists the FG sites and associated physiographic characteristics. The majority of the FG sites lie in alluvial surface deposits (Detterman and Reed, 1973; Hamilton, 2007).

6.2.2 FIELD DATA COLLECTION

The FG sites were sampled by two, three-person field crews. Data collected at each FG site included:

- Survey information required for hydraulic modeling.
- Pebble count data.

- Site photographs.
- Visual-based Manning's n roughness coefficient estimates.
- Bank material composition.
- Field notes.
- Qualitative estimates of bank vegetation type and density.

Survey teams walked each site, flagging from five to 11 individual cross-sections for the creation of a hydraulic model. Cross-sections were located that reflected breaks in slope, changes in channel or floodplain roughness, and channel expansion or contraction. Each topographic survey included: reference reach cross-sections, a downstream hydraulic boundary, vegetative lines, tops of banks, longitudinal profiles, water surface profiles, and temporary benchmarks.

Survey data were collected using a Sokkia Total Station survey instrument recording X, Y, Z data sets, which provided each recorded point with a vertical and horizontal location (based on a relative datum). A Garmin GPS Map 76CSx, handheld GPS was used to document the locations of established temporary benchmarks, pebble counts, and bulk samples.

A site sketch was completed at each site showing the channel, location of the model cross-sections, location of the bank soil profile, and location of the pebble count. Detailed map books of the aerial photographs, created and provided by HDR, were used to mark the sites and illustrate the locations of the cross-sections.

Details on specific field measurement procedures are provided below.

6.2.2.1 TEMPORARY BENCHMARK ESTABLISHMENT AND GPS LOCATIONS

At least two temporary rebar benchmarks were established at each FG site in case supplemental survey work was required. Benchmarks were considered reliable only for the 2007 field season due to frost heave. Their locations were surveyed and entered into a handheld GPS unit to incorporate the location and relative survey data into ArcMap for analysis and presentation.

6.2.2.2 REFERENCE REACH CROSS-SECTIONS

Reference reach cross-sections were generally located at the upstream segment of each FG site over a riffle channel unit. The reference reach was identified by the team as representative of the general area. At a minimum, cross-sections at the upstream and downstream ends of the riffle were surveyed to represent the reference reach. Other channel units or cross-sections were included where the riffle was not well-defined and/or where the team determined that the units/sections were also suitable for calculating hydraulic geometry parameters.

6.2.2.3 DOWNSTREAM HYDRAULIC MODEL BOUNDARY CROSS-SECTION

A downstream hydraulic boundary condition cross-section was surveyed for the hydraulic model. The cross section was typically located at the crest of a pool tailout, or riffle crest where a normal depth approximation was assumed in the modeling. In some cases, additional cross sections were surveyed downstream of the hydraulic boundary cross-section when there appeared to be noticeable backwater

effects. Surveyed water surface profiles (hydraulic grade slopes) were compared with reach-average slopes obtained from the DEM. The DEM model slope was used for the downstream boundary condition instead of the field surveyed water surface slope in a few cases with noticeable backwater effects.

6.2.2.4 VEGETATION LINES

Vegetative indicators were surveyed to describe locations on the cross-section where changes in roughness occurred for input to the hydraulic model, and to assist in identifying the stage corresponding to bankfull flow as predicted by the hydraulic models. Vegetative indicators included the transition from channel to grass or willow, changes from grass to willow communities, and the presence of mature trees.

6.2.2.5 TOPS OF BANKS

The locations of the tops of streambanks were noted on the cross-section on each side of the channel, reflecting the approximate bankfull flow level and changes in hydraulic modeling roughness conditions.

6.2.2.6 LONGITUDINAL PROFILES

The longitudinal bed and water surface profiles were surveyed through all cross-sections. The profile survey continued downstream to include a downstream riffle. Bed profile data were surveyed along the thalweg (deepest part of the channel). The water surface profiles were used to estimate energy grade slope for the hydraulic model at the downstream boundary transect.

6.2.2.7 STAGE-DISCHARGE DATA

Instantaneous discharge measurements and water surface data were collected for a range of discharges at three FG sites located near active stream gages to develop stage-discharge rating curves for use in hydraulic model calibration.

6.2.2.8 PEBBLE COUNT

Wolman pebble counts were conducted across each reference reach (generally in a riffle) between the edges of right and left bank vegetation. Counts involved measuring the b-axis (intermediate diameter) of 100 randomly selected rocks across the bar or bed feature (Wolman, 1954; Kondolf, 1997). In some cases, more than one pebble count was conducted to assess grain size distributions at different locations near the FG site, such as point bars (gravel bars located at the inside of a meander bend generally adjacent to a pool), or at developing banks above point bars. The data were ranked and various percentile particle sizes computed including D_{50} and D_{84}, where D_k is the particle size for which *k* percent is finer (e.g., D_{50} is the rock size where 50 percent of the rocks are smaller).

6.2.3 REMOTE SENSING ANALYSIS

Stream centerline shape files were converted to points in ESRI's ArcView v9.2 and used to extract elevation values from the DEM in order to create a longitudinal profile of the NFK, SFK, the mainstem Koktuli River just below the confluence of NFK and SFK, UT, and the three tributaries where fluvial geomorphology study sites were located. The drainage area was defined for each field data site as the portion of the watershed contributing water to that location along the individual river network. HDR

calculated drainage area for sites sampled by HDR and IFI using ArcHydro, an ESRI ArcView extension, and the Pebble Project DEM.

6.2.4 HYDRAULIC MODELING

Hydraulic model development consisted of reducing the field data into a form that could be input into Hydraulic Engineering Center River Analysis System (HEC-RAS), a 1-dimensional hydraulic model. The model was calibrated at selected sites where sufficient suitable data existed and the results used to guide model parameter specification at the other sites. The models were run to predict stage and discharge, and the results interpreted to identify a 'channel forming' flow estimate. Details regarding each step in the analysis are provided below.

6.2.4.1 FIELD DATA REDUCTION

Cross-section **s**urvey data coordinates were converted to a common horizontal datum (North American Datum [NAD] 83 Alaska State Plane Zone 5), but kept to a local vertical datum specific to the site. Survey data were collected as three-dimensional (X,Y,Z) coordinates and converted into station elevation data characteristic of cross-section profiles running perpendicular to the stream. Since the raw survey data were not collected along a perfectly straight line extending perpendicular to the stream-wise direction, as required for hydraulic modeling, the horizontal (X,Y) coordinates were first adjusted to fit a straight line by projecting each point perpendicularly onto the line. Apparent errors in field data recording (e.g., rod height errors and incorrect stationing based on the proximity of survey points to each other) were corrected during this process. Locations were noted along each cross-section corresponding to toe and top of bank, approximate bankfull location based on field observations, thalweg, water's edge, and overbank. Thalweg and water surface elevation data and the intervening upstream-downstream distance between point locations were used to calculate bed and estimated energy grade slopes, respectively.

6.2.4.2 HEC-RAS MODEL DEVELOPMENT

A steady-flow HEC-RAS hydraulic model was created for each site. A geometry data file was created that included cross-section station-elevation coordinates, channel roughness, and bank stationing. The data file also included a definition of any ineffective or blocked flows determined in the field. A steady-flow data file was created that defined simulation discharges and downstream boundary conditions.

Cross-sections were labeled in increasing order from downstream to upstream, and were defined by station elevation pairs progressing from left to right across the channel as viewed looking downstream. Within each model, the top-of-bank stations, or the location on each bank defining the active channel width, were noted. These locations were chosen based on three indicators: an inflection point in the geometry of the channel, a vegetative line, or survey notes indicating top of bank. Generally, at least two of these indicators correlated well. For a few FG sites, the bank stationing locations were not clearly distinguishable. For these sites, the best indicator representing the active channel width was identified through consensus discussions of available visual evidence.

Channel and floodplain roughness were quantified as "Mannings n-coefficients", with horizontal variation across the channel described using a model option in HEC-RAS. Vegetative lines were delineated in the survey to define the location of changes in roughness coefficient value across the cross-section profile. The channel roughness coefficient was derived for the known stage and discharge given known cross-

section properties (also see section 6.2.4.4). Floodplain roughness was determined for general vegetation classes through professional judgment of three IFI hydraulic engineers, based on a combination of experience and methods described in Arcement and Schneider (1987) and Barnes (1967). Attachments 1 and 2 summarize the results for channel and floodplain, respectively. The attachments present results for selected sites that were relied on for estimates of Mannings n values that could be applied to other sites.

Ineffective flow boundaries were defined in the geometry file for selected cross-sections where portions of the profile did not appear to contribute significantly to conveyance around the bankfull flow level (e.g., in backwater areas with only one connection to the main channel). In locations where flow was confined by natural levees (elevated depositional features running parallel to the stream), the natural longitudinal embankments were modeled using the levee feature in HEC-RAS.

The HEC-RAS hydraulic model requires assignment of a downstream boundary condition for sub-critical flow modeling. The normal-depth approximation was applied as the boundary condition using either the field surveyed or DEM-derived estimate of the reach energy slope. Field surveyed slopes were either locally determined at well-defined downstream hydraulic control locations, or the average slope value for the site or between riffle crests. An initial independent review for the Pebble Project by N. Braithwaite (Pacific Hydrologic Inc.) indicated that the exact value of the slope did not substantially change upstream predictions of water surface elevation at the reference transect.

6.2.4.3 HEC-RAS MODEL FLOWS

The HEC-RAS backwater models were run for a range of discharges in order to develop an understanding between flow and other channel hydraulic characteristics including width, depth, and incipient motion criteria. The models were initially run using a wide range of flows and subsequently refined to reflect a narrow range of flows surrounding a channel forming flow estimated from the three active channel indicators described in Section 6.2.4.2. Reference reach hydraulic data from the backwater models were subsequently used for an incipient motion analysis to verify that the channel forming flows estimated from active channel indicators were adequate to exceed incipient motion criteria. The magnitude of the channel forming flow in gravel bed rivers is expected to be larger than the incipient motion flow magnitude, because sediment transport typically begins somewhere between 60 to 100 percent of the bankfull flow (Wolman and Miller, 1960; Schmidt and Potyondy, 2004).

6.2.4.4 HEC-RAS MODEL CALIBRATION AND SIMULATION

Manning's roughness coefficient, *n*, was calibrated to the narrower flow range about the initial estimate of the channel forming flow at three sites, using established stage discharge rating curves. The results of the calibration were used to adjust visual-based estimates of roughness coefficients at other sites. Roughness values were chosen for other sites based first on the calibrated roughness values. The values were compared with a range of values derived using several methods including comparison with empirical measurements (Barnes, 1967; Jarrett, 1984; Hicks and Mason, 1991) and following a roughness partitioning approach (Chow, 1959; Arcement and Schneider, 1987).

6.2.5 DEVELOPMENT OF HYDRAULIC GEOMETRY RELATIONSHIPS

Values of wetted width and hydraulic depth (area/width) were derived from the HEC-RAS modeling for the estimated channel forming flow. Channel width was calculated as the effective top width of the

reference reach during the nominal channel forming discharge. This corresponded roughly to the top width of flow confined between the top-of-bank stations within the active channel. A nominal channel width was determined as the average of all reported top widths at reference reach cross-sections through the range of channel forming discharges as a way to account for variability and uncertainty. Sections where ineffective flow areas were defined in the model were not included. Additional exceptions exist where bedforms were not clear and a well-formed riffle was absent. In these cases, all cross-sections through the site, with the exception of Section 1 which served as the downstream boundary, were averaged over the range of flows. The nominal wetted channel cross-sectional area was determined in the same way as nominal width. A nominal hydraulic depth was computed by dividing the nominal width value into the nominal cross-section area value.

The resulting channel forming flow, width, and depth estimates were converted to dimensionless form via (Parker et al., 2007):

$$\hat{B} = \frac{B_{bf}}{D_{50}} \quad [1]$$

$$\hat{H} = \frac{H_{bf}}{D_{50}} \quad [2]$$

$$\hat{Q} = \frac{Q_{bf}}{\sqrt{gD_{50}}\,D_{50}^{2}} \quad [3]$$

Where:

B_{bf} = bankfull width

D_{50} = particle size in the riverbed surface for which 50 percent of the material is finer

H_{bf} = bankfull hydraulic depth (area/width)

Q_{bf} = bankfull flow

g = acceleration due to gravity

The resulting dimensionless quantities were compared with published data from other gravel bed rivers, and regressed for various groupings of sites.

The dimensionless channel morphology parameters were plotted and regressed with channel slope against the dimensionless channel forming flow estimate. These values were also regressed with other dimensionless hydrologic flow parameters representing potentially geomorphically relevant flow levels. These included the estimated 5 percent and 1 percent exceedence flow levels (general range of onset of motion conditions in alluvial channels), and the 2-year and 10-year flood event peak flows (general range of geomorphically effective flows for a variety of channel types; Williams 1978). Two sites (FGSK124-1 and FGSK6) were excluded from further analysis after it was determined that the hydraulic model data were insufficient for estimating minimum channel forming discharge.

6.2.6 TRIBUTARY HABITAT DATA

Tributary habitat surveys conducted by HDR and, subsequently, R2, included data useful for describing broad spatial trends in selected characteristics of sediment supply to the three main study rivers, including general grain size and sediment transport potential. Field methods for collecting the habitat data are described in Chapter 15 of the EBD. Relevant data collected included: pebble counts, general substrate composition expressed as percent of streambed area, approximate bankfull width and depth in the vicinity of pebble counts, and local stream slope. The bankfull width, depth, slope, and grain size data were used to compute dimensionless bankfull width and depth using equations [1] and [2], and flow using equation [3], where flow rate was approximated using Mannings equation with an assumed bankfull Mannings n_{bf} =0.07 (SI Units):

$$Q_{bf} \approx B_{bf} D_{bf} \frac{1}{n_{bf}} D_{bf}^{2/3} \sqrt{S} \qquad [4]$$

Where:

D_{bf} = bankfull depth

S = Reach slope estimate

The results were compared with the quasi-universal hydraulic geometry data of Parker et al. (2007) to evaluate whether the field observations of bankfull were reasonable and could be used in future assessments of tributary sediment supply to the mainstem river channels.

As a screening level assessment, the pebble count D_{50}, and ocular estimates of percent sand and percent gravel, were plotted spatially in GIS to evaluate spatial patterns in potential fine and coarse sediment inputs to the mainstem channels within the area bounded by the three study rivers.

6.3 PARTICLE MOBILITY STUDY

During a flood, the water imparts shear stresses on the riverbed that at some threshold flow become sufficiently strong to begin moving the river bed material. This is termed the process of incipient motion. The absolute value of shear stress required to move a bed particle generally depends on the particle's size and how it is packed in the bed surface. This process of incipient motion is not strictly an 'all-or-none' threshold. In natural riverbeds, incipient motion can be assessed in terms of specific measures of the bed grain size distribution and an estimate of the shear stress acting on the bed. Typically, incipient motion is described using a dimensionless representation of shear stress, termed the critical dimensionless, or Shields (1936), shear stress t^*_{cr}:

$$\tau_{cr}^{*} = \frac{\tau_{cr}}{(\gamma_s - \gamma)D} \qquad [5]$$

Where:

t_{cr} = the critical shear stress on the bed

γ_s = the specific weight of the bed particles

γ = the specific weight of water

D = a characteristic particle size, usually expressed as the D_{50} value for the bed.

Conceptually, the Shields stress represents a balance between the mobilizing force (shear stress) and resistance to motion (particle weight). Given that incipient motion typically occurs somewhere between 60 to 100 percent of the bankfull flow (Schmidt and Potyondy, 2004), knowledge of the value of t^*_{cr} is useful for:

- Assessing the minimum possible channel forming flow magnitude estimates.
- Assessing channel stability and computing sediment transport rates in general when analyzing flow scenarios.

A pilot analysis of incipient motion conditions conducted in 2005 suggested general immobility of the bed during the initial estimated channel forming flow, based on an average published value of t^*_{cr} equal to 0.047 (Buffington and Montgomery, 1997). This result did not appear to be consistent with field observations of general bed mobility conditions, which suggested a lower value of t^*_{cr} might be possible. A particle mobility study using radio-tagged rocks was, therefore, conducted in 2007 to investigate this further at one site on the NFK.

6.3.1 STUDY SITE

The radio rock study was conducted at FG site FGNK2 (Figure 3). The site was selected because it was co-located with a USGS stream gage on the NFK, and had a relatively straight section of channel near the gage to simplify the hydraulic conditions as much as possible. The downstream portion of the site is in a bend of the river.

6.3.2 RADIO ROCK PREPARATION AND DEPLOYMENT

Nineteen radio-tagged rocks were deployed on September 15, 2007, and were spaced approximately 10 feet apart across the bed along two transects (Figure 3). The transects were located approximately 200 feet downstream of USGS gaging station 15302250. The rocks were selected to represent the D_{50} and D_{84} surface sediment size classes determined from a pebble count conducted across the reference riffle at FGNK2 during the July 2007 field work.

A Lotek Wireless radio telemetry system was employed to track the movement of selected rocks at the site. The system used coded motion sensor radio transmitters or radio tags (Model SR-M11-12) with a motion reset switch, a stationary receiver/datalogger (SRX600), and a five-element Yagi antenna (F150-5FB). The Lotek system uses a unique code to identify each radio tag. Because the radio tags were always in contact with the SRX600, and the SRX600 could only read one tag at a time, the 19 codes were spread out over five frequencies to ensure the receipt of each code (Table 2). The radio tags included a motion sensor reset switch to sense rock movement when the rock changed planes. Therefore, slight shifting in the same position would not activate the motion sensor; only the rolling of rocks would be recorded as movement. Once rock movement occurred, the radio tag transmitted an altered code value. The tag continued to transmit the altered code for 1 minute and then reset to the immobile code. The radio tags were programmed with the most sensitive activity criterion possible and with a 5.5-second burst rate.

The individual A-, B-, and C-axis dimensions of each rock were measured before drilling, and the weight and volume of each rock were measured before and after rock drilling and radio tag implanting (Table 2). Rocks were drilled using a 12.7-millimeter (mm) diameter, diamond core drill bit. The drilling depth was between 42 millimeters and 45millimeters. The transmitters or radio tags used in this study were 11millimeters in diameter and 41millimeters in length. Nine D_{50}-sized rocks and 10 D_{84}-sized rocks were successfully drilled and radio tagged. Radio tags were placed in the drilled holes and held in place with liquid epoxy glue. The radio tag antennas were 355millimeters long and were wrapped around the rocks and glued in place with more epoxy glue. The remaining void space left between the drilled hole and radio tag was left open to ensure no air was trapped within the rock. A rock of similar size was removed from the bed and the tagged rock was put in its place. The tagged rock was firmly pushed down into the adjacent substrate to approximate the condition of the untagged rock that was pulled out of the bed. The position of each rock was surveyed using a total station relative to the location of the hydraulic model transects.

The SRX600 was programmed to automatically scan through all five frequencies every 6 seconds for a total scan time of 30 seconds. During each scan period, the SRX600 logged each radio tag at least one time. The continuous record time out option was enabled, which compressed the data to a specified time interval. For this study, a 15-minute period was chosen to match the real-time discharge data from the USGS gage on site. The compressed data summarized the output from each unique code over the 15-minute interval. This provided the: code, time of the first reading, signal strength, number of events logged, and duration of the events.

A custom-built box was used to house the SRX600 and for mounting the antenna. The housing box was located 20 feet from the top of the right bank and slightly downstream of the initial rock placement. The SRX600 was set to pick up the highest number of radio tags with the least amount of noise. On-site evaluation of the radio tag reception and logging revealed that, at times, individual tag signals would overlap, logging noise instead of the radio tag codes. A 12-volt deep-cycle battery was connected to the SRX600 and placed with the SRX600 in the housing box. A solar panel provided a continuous charge to the battery. A second solar panel charged a bear exclusion fence surrounding the housing box and associated equipment.

6.3.3 DATA RECORDING AND ANALYSIS

The radio rocks were monitored from September 15 to 30, 2007, at which time the data were retrieved from the data logger. Preliminary, provisional 15-minute discharge data for this period were downloaded from the USGS web page in tabular format for the North Fork Koktuli USGS gage. Active and inactive codes were graphed for the same tag to evaluate data consistency. Discharge data were plotted alongside the instances of rock movement to provide a visual interpretation of the incipient motion of each particle. This information helped evaluate the initial rock movement for the incipient motion analysis.

To qualify as incipient motion, each radio rock had to:

- Move within the time frame of a flow event during the ascending limb of a peak flow event hydrograph (Wilcock and McArdell, 1997; Lisle et al., 2000; DeVries et al., 2001; Haschenburger and Wilcock, 2003; McNamara and Borden, 2004).

- Move at least once during subsequent events with flow levels as high or higher than the first flow at which the rock moved.
- Exhibit repeated motion.

Movements occurring before the first flow event were interpreted as the readjustment of the rock on the bed after initial placement. Rocks that moved a small number of times and/or in inconsistent manners compared with the periods of mobility suggested by the hydrograph were assumed to have been temporarily displaced through forcing—rather than the general shear stress associated with incipient motion conditions. This motion likely resulted from: impact by one or more smaller rocks, rolling and resettling to a more stable position, suspended debris catching the wrapped radio wire, or other extraneous influences. Additionally, mobility codes not preceded by consistent, immobile codes were disregarded. Without a signal from a given rock, mobile or immobile, it would be impossible to know if the rock began movement before the first mobile code.

Once a rock became immobile, the initiation of its next movement was counted as incipient motion subject to the conditions above. The date and time of incipient motion for each rock were matched with the lowest corresponding flow on the ascending limb of the hydrograph to identify an incipient motion discharge.

The position of the tagged rock on the transect was used to estimate the depth at the rock location at the incipient motion flow. The two cross-sections of radio-tagged D_{50} and D_{84} rocks were added into the existing hydraulic model and the predicted depth used to estimate local shear stress (τ_b), with depth substituted for hydraulic radius (R) in the uniform flow approximation:

$$\tau_b = \gamma RS \qquad [6]$$

The corresponding average critical Shields stress τ^*_{cr} was calculated as in equation [5] for each rock for the transect on which it was placed, based on the intermediate axis diameter where the specific weight of each rock was calculated by:

$$\gamma_S = \frac{w}{V}, \qquad [7]$$

Where:

w = weight

V = volume of the rock as measured before deployment

For rocks that did not move, the peak shear stress was calculated at the highest flow rate recorded during the radio rock study. The local shear stress at the rock location was estimated by first computing the average active bed shear stress in the HEC-RAS model, between the toe of the right bank and near the edge of the active gravel bar on the left bank. The estimated average bed shear stress was then multiplied by a ratio accounting for position along the cross-section profile, ignoring the additional effects of position along a bend on shear stress amplification (e.g., Chen and Cotton, 1988). The ratio was based on

the normal depth approximation of shear stress, and was equal to depth at the rock divided by the hydraulic depth. This yielded an approximation of the local shear stress at each radio rock's location.

Radio rocks were identified as having not moved, moved in a consistent manner with hydrograph timing and magnitude, or moved where movement may have been induced by a factor other than shear stress ('questionable'). The results were plotted in a histogram to assess the range of estimated Shields stresses over which movement did or did not occur.

6.4 FINE SEDIMENT LEVELS IN SPAWNING GRAVELS

The pilot study gravel samples collected in 2007 indicated the presence of relatively low levels of fines of the size influencing survival within the gravel (incubation stage). However, the sampling did not include replication. A more intensive study was, therefore, conducted by R2 in 2008 to assess statistically whether fine sediment levels within gravels used by salmon before spawning occurs were representative of conditions at the same location after streambed re-working through the combined effects of spawning fish, and high flows resulting from fall rains. Replicate spawning gravel samples were collected at sites on each of the three main river systems in the study area

6.4.1 SPAWNING GRAVEL STUDY SITES

Three Spawning Gravel Study (SG) sites were sampled on each of the mainstems of the SFK, NFK, and UT, for a total of nine sites (Figure 4). The sites were distributed upstream to downstream in known salmon spawning areas, where spawning activity was observed during sample collection. To the maximum extent possible, while still maintaining an even spacing along the river network, the SG sites were co-located with IF Study sites or with FG sites, as follows:

- The two lower sites on each of the SFK and NFK, and the upper site on the UT, were also IF Study sites.
- The upper sites on the NFK, SFK, and the middle site on the UT, were proximal to FG sites.

6.4.2 FIELD DATA

Fieldwork was conducted on two occasions to represent fine sediment levels: in spawning habitat before spawning-related disturbance of the bed, and following spawning and bed redistribution by high flows associated with fall rains. Because peak flows are generally associated with spring-runoff events, collecting samples during the first period provides a worst-case condition. The concentrations of fine sediments within the gravel matrix, in which fine sediments have infiltrated over a full annual cycle after spawning the previous year, would be the concentrations encountered by salmon as they commence spawning.

Samples collected post-spawning and post-fall rains were hypothesized to potentially contain different fine sediment concentrations than before spawning, because of both spawning activity and mobilization during high flows. In addition, flows resulting from the fall rains are generally of smaller magnitude than spring runoff, and were hypothesized to be more prone to fine sediment intrusion. Sampling gravel post-spawning and post fall-rains would reflect a set of conditions directly experienced by incubating eggs. Sediment levels within such samples would be more representative of conditions within the incubation

environment than the pre-spawning samples. Fine sediment concentrations within the spawning gravels could continue to increase throughout the incubation period, and would be expected to achieve sediment levels similar to those in adjoining, undisturbed areas. The sampling strategy selected was designed, in part, to determine how rapidly fine sediment levels in cleaned spawning gravels might return to background (mid-summer) levels.

6.4.2.1 SAMPLE SIZE

Six replicate gravel samples were collected from each SG site during the pre-spawning sampling. The number of replicates reflected a balance between precision and cost. A statistical power analysis conducted on the single sample/site pilot data collected in 2007 indicated that six replicates permitted evaluation of intra-site variability of fine sediment levels across the nine SG sites. Thus, a total of 54 samples (i.e., nine sites times six replicates) were collected to represent ambient conditions.

The number of post-spawning samples was minimized in consideration of possible impacts to developing embryos. The power analysis indicated that single post-spawning samples collected from each of the nine SG sites would be sufficient to identify temporal changes in spawning gravel conditions across the entire study area, assuming all sites exhibited similar variation. A contingency was developed in which if results of the pre-spawning sampling indicated significant differences existed in sediment levels between rivers, then the number of post-spawning samples could be increased up to a maximum of three replicates per site (27 samples total) if all rivers had significantly different levels of pre-spawning sediment. In the field, it was determined that the sampling could be conducted in a way to minimize impact to embryos (see next section) such that it was possible to collect up to three replicate samples per site.

6.4.2.2 SEDIMENT SAMPLING

Bulk gravel samples were collected using a plastic 30-gallon drum with both ends cut off, with sample weights of approximately 23 to 34 kilograms (50 to 75 pounds) for each replicate. This sample weight generally provides an unbiased measure of percent fines for a single sample (Church et al., 1987; Bunte and Abt, 2001). The drum was worked into the bed by rotating and pushing it simultaneously until water flow inside was negligible. Continuous pressure was kept on the edges of the drum as the substrate was excavated by hand and transferred to a sample bag provided by Alaska Test Labs. The bag was sufficiently porous to allow water exfiltration with minimal loss of a small amount of ultrafine sediment.

Sample collection was consistent with the pilot study, where the surface and subsurface layers were collected and stored separately. The main difference with the pilot study was that the sieving results from the two spawning gravel sample layers were combined to meet a 5 percent unbiased sample weight criterion (Church et al., 1987). The surface armor layer was collected first and placed in a labeled sample bag and sealed. The exposed sub-surface layer was then excavated and placed in a separate labeled sample bag and sealed. The sub-surface layer sample typically included fines material that settled downwards from the surface layer during sample collection.

Post-spawning sampling involved collecting samples from redd tailspills. Excavation of the subsurface sample continued until either: 1) a depth of approximately 15 cm was reached, which corresponds roughly to the top of salmon egg pockets (DeVries, 1997), or 2) more than two to three embryos were encountered. In both cases, the collected sample weight for the combined surface and subsurface layers

was sufficient for an unbiased estimate of percent fines following the 5 percent criterion of Church et al. (1987).

A pebble count was conducted at each site according to the methodology outlined by Wolman (1954). Pebble counts were performed to provide 1) a quality assurance/quality control (QA/QC) comparison with bulk sample results and 2) a more cost-effective and accurate characterization of streambed surface particle size distribution than bulk samples in coarser substrates.

For one sample at each FG and SG site, water inside the bulk sample collector was decanted after the subsurface layer sample was collected and a 1-liter sub-sample was drawn and poured into an Imhoff cone. The water-sediment suspension was allowed to settle for 30 minutes and the level of the deposited sediments recorded. The result served as an index of sediment concentration of finer suspended grain sizes, because the bulk sampler method does not allow an accurate characterization of ultrafine suspended sediment concentrations.

6.4.2.3 SIEVING AND DATA ANALYSIS

Sieving of the bulk samples was performed by Alaska Test Labs. Sieving methods were based on standards developed by the American Association of State Highway and Transportation Officials (AASHTO), and included:

- AASHTO T 255/T265 Moisture Content of Aggregate and Soils
- AASHTO T 248 Reducing Samples of Aggregate to Test Size
- AASHTO T 27/T11 Sieve Analysis of Aggregates and Soils

Sieve sizes used are listed in Table 3.

Cumulative grain size distributions (percent finer versus grain size) were computed for use in the present and in future geomorphology analyses. Distributions were computed for the: bulk sample surface layer, bulk sample subsurface layer, total bulk sample for both layers combined, and pebble count. For the SG study, the total bulk sample distribution was evaluated. The following metrics were calculated that are relevant to assessing the influence of fine sediments (cf. Lotspeich and Everest, 1981; Platts et al., 1979; Shirazi et al., 1981):

- Percent of total weight for sizes less than 0.84 and 6.4 millimeters
- Sorting coefficient $S_0 = \sqrt{D_{75}/D_{25}}$ [8]
- Geometric mean diameter $D_g = d_1^{p_1} * d_2^{p_2} * ... * d_n^{p_n}$ [9]
- Fredle index = D_g / S_0 [10]

Where:

d^{Y}_{X} = Average grain size of class X, raised to the power Y where Y is the proportion by weight of the total mix represented by class X.

These metrics were compared with published research related to spawning gravel quality and survival-to-emergence results (Kondolf, 2000; Chapman and McLeod, 1987; Shirazi et al., 1981; Lotspeich and Everest, 1981; Reiser and White, 1988). The 0.84- and 6.4-millimeter criteria are generally associated with effects to incubation and emergence, respectively, where high levels of fines equate to low survival for each phase of the intragravel life stage. Substrates with higher geometric mean diameter and Fredle index values are generally associated with higher survival-to-emergence overall. Evaluating these various metrics provides a screening level indication of the quality of spawning gravels within the three major study area rivers, and an associated estimate of the range of expected survival-to-emergence within the rivers.

The amount of fines in spawning gravel samples collected before spawning was compared with those collected post-spawning and post-fall rains using a paired t-test. Results of these comparisons were used to assess temporal changes in gravel quality, as influenced by spawning activities and high flows associated with fall-rains.

6.4.2.4 SPECIFIC GRAVITY AND GRAVEL SOURCE LITHOLOGY

The specific gravity of gravel sub-samples from each SG site and selected FG sites were measured. This was done to assess if upstream-downstream differences existed that might reflect spatial variation in source lithology and sediment transport potential. Alaska Test Labs soaked samples in water for 24 hours, weighed the rocks in water, dried the rocks, weighed them again, and then calculated specific gravity and absorption values. The sub-samples were of stones retained by the 2-inch, 1.5-inch, 1-inch, and ¾-inch sieve sizes combined from surface and sub-surface samples from the following sites (Figures 2 and 4):

- SFK: SGSK1, SGSK2, SGSK3, FGSK12, and FGSK15
- NFK: SGNK1, SGNK3, and FGNK13
- UT: SGUT1, SGUT3, and FGUT10

The intent of this study element was to assess large scale trends across the study area. More samples were collected from the SFK because of the lower gradient and associated greater potential for spatial variation in response to tributary inputs compared with the other two streams.

7. RESULTS AND DISCUSSION

Fluvial geomorphic processes and conditions are manifest over a range of scales. This section begins with an overview of important geomorphic processes at the study area and basin scales (Section 1.1.7.1). Conditions and processes occurring at the river reach and site scales that are important to local channel morphology and fish habitat are investigated via a series of field-based studies focusing on channel geometry and hydraulic modeling (Section 7.2), particle mobility (Section 7.3), and fine sediment in spawning gravel (Section 7.4).

7.1 GEOMORPHIC VARIATION WITHIN AND BETWEEN MAINSTEM RIVERS

The results of the analyses and literature review indicate five ways in which fluvial geomorphic processes are manifest in each of the three primary river basins in the study area:

- **Physiographic and Planform Features.** There are geologic and morphologic differences at the segment scale between and across basins evident in plots of longitudinal profiles of elevation, geologic units, channel slope, valley confinement, and sinuosity. These differences influence physiographic and planform features, including channel migration patterns and processes.
- **Reach Scale hydraulic Geometry and Sediment Characteristics.** There are patterns in upstream-downstream variation in site-scale hydraulic geometry and sediment characteristics, evident in plots of bankfull dimensions and substrate characteristics.
- **Ice Processes.** There are upstream-downstream differences in ice-forming processes that reflect some of the physiographic features listed above and that, in turn, influence fish habitat quantity and quality during the critical winter survival period.
- **Beaver Activity.** Beaver activity in the mainstem and side channels reflects upstream-downstream location in the channel network, as determined primarily by channel size. This may influence the distribution of fish habitat quantity and quality during both the critical winter survival and spring and summer growth periods.
- **Sediment Sources.** Mainstem sediment sources include both tributaries and variously distributed eroding terraces, but the relative importance and input rates are unquantified. Fine sediment and gravel quantities in the three rivers appear to reflect tributary contributions to some extent.

These five processes are presented and discussed below.

7.1.1 PHYSIOGRAPHIC AND PLANFORM FEATURES

The NFK and SFK flow through glacial-origin valley bottoms with probable Holocene era alluvial sediment deposits, and their channels appear to be small (i.e., underfit) relative to the multiple stream terraces documented by geologic mapping (Detterman and Reed, 1973; Hamilton, 2007). Large amounts of sediment were flushed rapidly down the valleys during periods of deglaciation after the Kvichak and Liamna Stades of the Brooks Lake Glaciation, forming broad floodplains that the rivers subsequently cut through as the sediment load decreased. Like other streams entering Iliamna Lake, the UT is steeper and more deeply entrenched than the NFK and SFK and, thus, has a greater erosional tendency (Detterman and Reed, 1973; Hamilton, 2007). The lower elevation portions of each mainstem river generally flow through alluvial surface deposits.

Slopes in all three rivers are generally characteristic of pool-riffle and plane bed channels in gravel bed rivers (Montgomery and Buffington, 1997). Channel slopes are gentlest in the SFK and steepest in the UT (Figure 5). Channel slopes in the SFK range from 0.03 to 0.60 percent and average 0.22 percent in the FG sites. The portion of the mainstem SFK that flows through lacustrine surficial deposits has a relatively low gradient compared to the rest of the mainstem (Figure 6), with channel slopes on the order of 0.03 to

0.07 percent. This segment would be expected to have the greatest tendency towards sediment deposition and storage, which may limit gravel supply to downstream segments.

Channel slopes in the FG sites ranged from 0.09 to 0.84 percent and averaged 0.35 percent over the length of the NFK (Figure 7). There is a lower gradient segment (0.08 percent) downstream from Big Wiggly Lake (River Kilometer 85 to 89) that flows across mixed glacial outwash, drift, and lacustrine deposits upstream of a glacial moraine (Figure 7). This area represents an important geomorphic gradient break, where substrates are substantially finer than upstream and downstream. Within the silt ice rich surface geology mapping unit, the majority of the riverbed is composed of fine sand and silt, with intermittent fine gravel waves (D_{50} approximately 13 millimeters) present. All coarser material transported from upstream appears to deposit near the junction between the silt ice rich and upstream glacial outwash mapping units.

Channel slopes are steepest in the UT, ranging from 0.10 to 2.0 percent and averaging 0.45 percent in the FG sites (Figure 8). This reflects a greater net elevation change and the presence of bedrock controls and coarse riverbed material. Like the NFK and SFK, the headwaters of the UT flow across glacial lake deposits.

Channel forming flow estimates and channel slope data for the FG sites (see Section 7.1.2) were compared with slope: discharge relationships derived from rivers around the world (Leopold et al. 1995). Results suggests that the downstream portions of the NFK and UT tend towards a braided planform (Figure 9; downstream sites are associated with larger bankfull flows). Much of the SFK, and the headwater areas of the other two study rivers, appears to tend towards a meandering planform. There are departures towards a straight channel near the transition line of Figure 9. Whether a given segment possesses a meandering or braided versus a straight planform appears to reflect the relative extent of channel confinement by valley walls or relict upland terraces from glaciation. The degree of entrenchment is also a possible factor.

The sinuosity and confinement data indicate that the study rivers are generally straighter and less sinuous where the confinement is smaller because of valley width constraints (Figures 6, 7, and 8). The rivers meander more where floodplain width is substantially greater than the channel width. The UT generally tends towards straight channels, except where the valley width is greater and multiple channels can be found in these locations.

7.1.2 REACH SCALE HYDRAULIC GEOMETRY AND SEDIMENT CHARACTERISTICS

Longitudinal profiles of channel geometry (bankfull width and depth) and grain size distribution (D_{50}) parameters indicate broad scale sections of river exist where D_{50}, D_{84}, and bankfull width and depths tend to be similar (Figures 10, 11, and 12). Channel width to depth ratios tend to be larger in magnitude in downstream alluvial areas, and smaller in headwater areas with glacial lake and outwash influences, although the approximate change point in the figures does not appear to be completely linked to geology. It remains to be confirmed through ice modeling, but a current hypothesis is that the breakpoints may be related to differences in ice-forming processes, with complete freezing upstream and ice cover formation downstream of the general break point location (Best et al., 2005; see Section 7.1.3).

Dimensionless widths and depths are generally smaller in magnitude in the respective lower gradient sections of the NFK and SFK, although the magnitude is several times larger in the SFK than in the NFK (Figures 10 and 11, respectively). Upstream-downstream differences in channel geometry and grain size are more uniform in the UT, which also contains coarser substrates than the other two study rivers (Figure 12).

7.1.3 ICE PROCESSES

Much of the length of each study river freezes every year during the winter. The physical patterns and locations of freezing influence suitability of over-wintering habitat for fish to varying extents throughout the channel network. Ice-free segments have been documented in all rivers, particularly where pronounced groundwater inflows exist (HDR, unpublished data), and likely represent important refugia for overwintering fish.

There are currently insufficient data to quantitatively describe upstream-downstream variation in ice forming processes in the study area with confidence. Therefore, this section describes ice-forming processes and linkages with fluvial geomorphology in the study area in a qualitative context, relying primarily on general knowledge in the scientific and engineering literature, but with site-specific, opportunistic observations included where possible.

7.1.3.1 VARIATION IN ICE PROCESSES ACROSS SPATIAL SCALES

At the basin scale, there is likely to be a general location in each of the three major river channels upstream of which the entire water column becomes frozen, and downstream of which a floating ice cover forms and is maintained until spring melt. The location will reflect a balance between channel depth and potential ice thickness that reflects air temperature and the number of degree days below freezing (USACE, 1981; Prowse, 2003a; Ettema and Daly, 2004; Best et al., 2005). Thus, the location will essentially reflect channel size, elevation, flow, and local climate. Within the upstream reach, there may be a sub-reach transition location where upstream the entire channel becomes frozen, and downstream pools may have a thick ice cover while riffles and runs freeze completely.

Within the larger scale downstream reach where an ice cover predominates, the thickness of the cover relative to flow depth will generally decrease in the downstream direction (Ettema, 2002). Therefore, the influence of ice breakup and ice jams on the channel bed and banks may be expected to vary from upstream to downstream. Steeper, turbulent riffle locations in the upstream sub-reach may experience development of frazil and anchor ice sooner and more extensively in the winter than downstream riffles (Shen, 2003), and frazil ice transport may have greater influence on freezing processes and fish habitat availability in pools upstream compared with downstream (Prowse, 2003b).

While channel geometry at the reach scale has been determined to influence ice formation and breakup processes, it is unclear at present the extent to which channel geometry properties, in turn, may be affected by ice processes (Ettema, 2002; Prowse, 2003a; Ettema and Daly, 2004; McNamara and Kane, 2009). At the broadest scale, there may be a discontinuity in plots of hydraulic geometry parameters against measures of channel size corresponding to the transition location from complete freezing of the water column to establishment of an ice cover (Best et al., 2005). There is no general agreement to date, however, on whether the processes whereby ice contributions to bank erosion may lead to a general channel widening tendency compared with open water channels (Ettema, 2002; Prowse, 2003a; Ettema

and Daly, 2004). There are various processes acting in opposition, the interaction and net effect of which on reach scale channel form are not well understood.

For example, willows and other vegetation appear to recolonize exposed surfaces quickly in the study area. Therefore, any widening that does occur locally may be balanced by deposition and vegetation establishment on the opposite bank, and the channel may adjust back to its more or less open water condition (Ettema, 2002; Prowse, 2003b). Actively eroding banks are frequently found on the outside of meander scrolls associated with willow thickets growing on point bars. Willows that become established on gravel bars form distinct succession lines along the stream margin (Photo 1) and trap sediments that continue to build the bar (Photo 2).

In some cases, ice jams that form at meander bends may cause erosion along the inside of the bend by the rerouted water (Smith and Pearce, 2002; Prowse, 2003a). Conversely, overbank flow associated with ice jam formation may favor channel narrowing because of reduced sediment transport capacity (Ettema, 2002). Available evidence to date does not indicate a strong effect of ice on channel geometry that results in substantially different relations from alluvial channels in general (Ettema, 2002). Instead, the rate and style of channel migration may be influenced by ice formation and breakup more than the size of the channel at the reach scale is. Boucher et al. (2009) recently suggested that the frequency of ice jam formation may be an important control on whether or not an influence of ice on hydraulic geometry is apparent in smaller watersheds, but it remains to be seen the extent to which this may apply to the study area rivers.

At the site scale, ice formation and breakup may influence local channel depth, bank stability, riparian vegetation, and channel migration mechanism. Ice jam development and induced bank scour appear to be localized conditions that vary in intensity and location across years in the study area. Bank ice formation can lead to local bank collapse, and ice jam formation may result in local bank and bed erosion. However, banks in the study rivers also freeze, which together with woody riparian vegetation such as willows may provide resistance and stability countering more widespread erosion. In addition, scour holes that form under ice jams tend to fill after breakup, such that the geomorphic signature and influence of the jam may not be obvious (Ettema, 2002; Prowse, 2003a, b).

Ice jams that form in channel segments with tight meander loops and split channels can be prone to building up, such that the river avulses and creates a new channel around the jam location. In segments with a broader meander, ice jams may lead to deposition along the banks and formation of elevated and over-steepened banks (Ettema, 2002; Prowse, 2003a, b). These processes appear to occur in various segments of the three study rivers based on visual observation.

Miscellaneous effects of ice formation and breakup on bedload transport include the entrainment of cobble and gravel by anchor ice sheets, and the entrainment of larger cobble and boulders through the formation of ice skirts or shells that effectively increase fluid drag forces (Oatley, 2002; Prowse and Culp, 2003). Cobble and gravel entrained by anchor ice has been observed in the study area to have been deposited on the floodplain surface, likely in response to ice jam formation. This deposition can lead to development of a stable floodplain surface (Prowse and Culp, 2003). Ice skirts and shells could be a primary mode of mobilization of larger lag deposits from the Brooks Lake Glaciation (Hamilton, 2007). These deposits appear to be distributed particularly in the lower segments of all three rivers (extending roughly downstream of sites FGNK7, FGSK7, and FGUT5), and downstream of larger landslide deposits.

These effects are probably minor in the study area from a larger scale geomorphic perspective but, nonetheless, contribute to overall mobility of the river bed.

7.1.3.2 INFLUENCES OF ICE PROCESSES ON FISH AND RIPARIAN HABITATS

Stream-wise and channel size-dependent differences in freezing and breakup processes have varying implications on channel morphology and survival of different life stages of salmonids. In general, complete freezing of the water column reduces habitat space. Unless groundwater influence is sufficient, both juvenile and intra-gravel incubation life stages of salmonids can experience substantial mortality. Thus over-winter survival in upstream spawning reaches that freeze down to the bed in the three study rivers may strongly depend on groundwater input to the channel. Anchor ice that forms from penetrating frazil ice can extend downward into spawning substrates. Juveniles are known to seek shelter within the riverbed substrate or in pools and, like developing embryos, may be vulnerable to freezing in such reaches (Prowse, 2003a, 2003b; Prowse and Culp, 2003).

In intermediate channel reaches where the water column is frozen, except in pools, the amount of frazil ice entering the pool may limit suitable over-wintering habitat space that fish key in on to minimize energy expenditure. In larger channel reaches, development of frazil ice can lead to avoidance behavior by some species such as Arctic grayling that may migrate downstream to more favorable habitat (Prowse, 2003b).

Prowse (2003b) noted that the upper limit to ice action can determine the lower limit of tree growth along river banks. However, willows can re-establish rapidly from residual roots in the banks, thus revegetation bank sections denuded by ice scour.

7.1.4 BEAVER ACTIVITY

7.1.4.1 VARIATION IN BEAVER DAM LOCATION ACROSS SPATIAL SCALES

Beaver can have a significant influence on channel morphology and hydraulics. Beaver dams are typically built across streams in places where the depth is less than about 0.6 meters, and generally not found where depth exceeds about 1 meter (Collen and Gibson, 2001). This is generally consistent with available habitat data collected in the study area, where beaver are ubiquitous throughout the river systems, and appear to have a profound effect on flow and habitat conditions. Analysis of aerial photos indicates that beaver may build dams spanning the main channel in the headwaters of all three river systems.

Similar to ice forming processes, there appears to be a transition location in each of the three study rivers, downstream of which the channel is too big and hydraulic and/or ice forces are too strong for beaver to successfully maintain dams. Identifying the downstream-most location of beaver dams that span the main channel indicates that this transition location occurs at a drainage area of approximately 10, 18, and 11 square miles in the NFK, SFK, and UT, respectively. The location of the downstream limit to main channel dams appears to be roughly associated with the downstream extent of lower gradient segments flowing through glacial lake deposit mapping units in the NFK and UT, and near the junction between glacial lake deposit and alluvium with sand content mapping units in the SFK (Figures 6, 7, and 8; Hamilton, 2007). The larger drainage area in the SFK may reflect hydrology differences and flood attenuation effects of Frying Pan Lake. Downstream of the transition point, the geomorphic influence of

beaver shifts primarily to off-channel habitats, where they dam abandoned channels and create off-channel ponds.

Relationships between beaver activity and fluvial geomorphic processes are not documented quantitatively for the study area, but beaver can be important influences on fish production when geomorphic and riparian conditions support them. Beaver require access to water with sufficient depth to allow construction of a winter food cache and to ensure the entrance to their burrow or lodge remains submerged. In addition, their range and distribution are controlled by the availability of woody plants to use in dam construction and for food, particularly willows, birch, and poplar/cottonwood. Where alder prevails, they use it primarily for dam building rather than food. They can build dams in a variety of streams from flat to steep gradient, and tend to use up local woody plant resources and then move on. Dam construction can influence stream channel morphology through local deposition of fines and trapping of gravel, and the death of submerged riparian vegetation and re-establishment of new vegetation at the margins of the impoundment. Flood hydrographs may be attenuated with enough cross-stream dams, although flooding may become more severe downstream temporarily during a dam burst (Murphy et al., 1989; Collen and Gibson, 2001). There may also be subsequent increases in sediment transport and channel erosion through dam bursts.

7.1.4.2 INFLUENCES OF BEAVER ACTIVITY ON FISH AND RIPARIAN HABITATS

Beaver ponds in the study area can provide important overwintering habitat for juvenile salmon and, in smaller stream channels, may provide the majority of unfrozen habitat (Murphy et al., 1989; Collen and Gibson, 2001). In addition, beaver ponds may be associated with increased growth rates of juvenile salmon compared with main channel fish, and support more fish per unit area. In some cases, beaver dams may impede or delay upstream passage of early fall spawning salmon to spawning grounds. However, species that migrate upstream during higher flows are often able to negotiate beaver dams. Juveniles are sometimes able to swim through leaks in the dams.

Beaver dams constructed across spawning grounds can remove those grounds from production through subsequent siltation of spawning gravels in lower gradient streams. At the same time, beaver dams may in some cases enhance spawning habitat by trapping fine sediments and reducing infiltration in redds some distance downstream. In streams with higher gradients (up to about 15 percent), beaver dams may contribute to spawning habitat formation by providing increased depositional opportunities in reaches with otherwise high sediment transport potential that tend to rapidly route gravel downstream, (Olson and Hubert, 1994; Collen and Gibson, 2001).

7.1.5 SEDIMENT SOURCES

The overall topography of the study area is relatively gentle. Sediment appears to be delivered to mainstem river channels from tributary streams, as well as from the erosion of alluvial banks and high streamside terraces adjacent to mainstem channels. Sediment sources and input volumes influence both sediment transport rates and aquatic habitats, particularly spawning areas. The major sediment sources identified within the study area are described below.

7.1.5.1 TRIBUTARY SEDIMENT SOURCE CHARACTERISTICS

Tributaries deliver fine and coarse sediments to the mainstem rivers. Transport capacity and the way in which the tributary drainage network is connected to the mainstem can influence channel morphology and habitat quality downstream. The location, size, and physical characteristics of each tributary determine its relative importance to mainstem fluvial geomorphic processes and conditions. This study relied on data collected primarily from tributaries draining the area in the vicinity of the Pebble Deposit in support of fish habitat assessments. Tributary sediment transport characteristics are also discussed further in Section 7.2 in relation to channel geometry.

Pebble counts and ocular surveys of bed composition suggest that tributary sediment inputs to the mainstem rivers vary across the study area, but may influence fine sediment concentrations and spawning gravel availability in the mainstem channels. Pebble counts of in-channel deposits indicate relatively smaller substrates in many UT tributaries and larger substrates in NFK tributaries, as represented by the bed material D_{50} (Figure 13). In the SFK drainage, pebble counts indicate smaller substrates in tributaries above Frying Pan Lake. Substrates in Tributary 1.190, downstream of Frying Pan Lake, are generally larger which may reflect the size of the stream. Several surveyed tributaries in the UT drainage appear to have relatively high sand and silt contents, whereas surveyed tributaries in the NFK drainage generally appear to have low sand and silt contents (Figure 14). All tributaries contain and likely convey gravel of a size suitable for spawning to varying extents (Figure 15), but the rates of supply to mainstem channels are unquantified. Notably, tributaries north of Frying Pan Lake contain relatively large quantities of gravel that are intercepted by the lake (Figure 15). In general, tributaries with steeper gradient or higher flows would be expected to export more sediment than smaller, lower gradient tributaries

7.1.5.2 MASS-WASTING AND BANK EROSION

In addition to tributaries, other potentially notable point sources of gravel and fine sediments include sections of the mainstem cutting into glacial outwash terraces. The outwash terraces consist of older surficial deposits and are higher in elevation than the geologically younger alluvial river banks. Vegetative cover on the terraces is generally thinner and consists primarily of tundra scrub vegetation. The rooting depth is shallow relative to the height of the terraces, providing relatively poor bank protection as compared to the more deeply-rooted shrubs common on lower alluvial banks. As a result, when river channels are located adjacent to high terraces, they rapidly undercut the toe slopes. This results in oversteepened side slopes with greater bank exposure than alluvial banks. Such areas tend to be prone to ravel and small landslides, as well as to contribute gravel and fine sediment directly to the channel where they occur (Photo 3). The total amount of sediment contributed by the exposed surfaces is unknown and has not been quantified for relative importance via a sediment budget.

Geologic mapping efforts also identified several deep-seated landslide deposits along the east side of the UT on the southeast side of Groundhog Mountain (Hamilton, 2007). These deposits may represent important local sources of sediment consisting of angular cobble and gravel within a matrix of finer sediment.

7.2 CHANNEL GEOMETRY AND HYDRAULIC MODELING

Initial or nominal estimates of channel forming discharge, width, and hydraulic (mean) depth are listed in Table 4 for the FG sites, as derived using the HEC-RAS models. Estimates of channel-forming discharge

were based, in part, on the requirement that they (at a minimum) equaled or exceeded flows approximating the condition of incipient motion of the D_{84} particle size. These estimates likely define a lower bound, because the condition of incipient motion in gravel bed streams occurs somewhere between 60 to 100 percent of the bankfull flow, which roughly corresponds to the characteristic channel forming flow (Schmidt and Potyondy, 2004). There appears to be considerable uncertainty in the nominal channel forming flow, width, and area estimates, as indicated by the range of possible values given in Table 4. In general, the uncertainty about the channel-forming flow estimate was greater at sites where incipient motion analysis results were least consistent with perceived channel geometry and inundation patterns. Summaries are provided in Attachment 3, including hydraulic modeling data and results and an overview of the selection of the nominal value and range of channel forming discharges.

Comparison of the channel-forming flow and hydraulic geometry estimates for mainstem channels, with a range of data compiled and analyzed by Parker et al. (2007), indicates that channels in the study area are representative of typical gravel bed rivers (Figure 16). The Parker et al. (2007) data include rivers from Alberta, Idaho, and Colorado that variously freeze in the winter and where ice is expected to have similar interactions with channel morphology. In general, the study area rivers appear to have hydraulic geometry relationships consistent with other gravel bed streams and may, therefore, be analyzed and described through regression analysis.

Comparison of the dimensionless hydraulic geometry parameter approximations for tributary fluvial geomorphology study sites with the data of Parker et al. (2007) suggests that the tributaries follow similar patterns as the main channels (Figure 17). The estimates of bankfull depth and width could be used in future more detailed analyses of sediment transport potential. However, the large scatter and positive bias seen in the slope data points suggest that the estimates of slope derived using clinometers are of low accuracy for evaluating bankfull discharge characteristics. Therefore, future studies of tributary inputs would require more detailed data collection.

7.2.1 CHANNEL FORMING FLOW REGRESSIONS CLASSIFIED BY BASIN

Estimates of bankfull wetted width and hydraulic depth (area/width) derived from the HEC-RAS modeling were plotted and regressed against the channel forming flow estimate and other hydrologic metrics representing potentially geomorphically relevant flow levels. Each regression for a given basin is statistically significant ($P<0.001$; adjusted r^2 values are 80 percent and better). However, the data do not indicate significant differences exist in channel geometry relationships between study river basins (Figure 18). The regression intercepts and slopes are not significantly different (alpha = 0.05). Therefore, the three basins appear to exhibit similar channel-forming processes and responses to changes in geology, hydrology, and sediment supply.

7.2.2 CHANNEL FORMING FLOW REGRESSIONS CLASSIFIED BY CHANNEL SLOPE

Parker et al. (2007) identified three major factors potentially influencing the relationship between the hydraulic geometry and bankfull flow depicted in Figure 17:

- **Bank strength**: Influenced by riparian vegetation, material properties, and freezing, where more resistant banks will tend to be associated with deeper and narrower channels.

- **Channel resistance**: Influenced by channel bottom cross-section and longitudinal profile irregularity (or, 'bedform drag'), where greater resistance is associated with deeper, less steep channels but does not appear to influence width.
- **Gravel yield**: Influenced by supply and transport from upstream and local bank and bed deposit sources, where increased gravel supply is associated with wider, shallower, and steeper channels.

The factors can be used to classify streams into different groups for which hydraulic geometry regression relations can be developed. The regression relations can then be used in subsequent assessments of potential effects of changes in hydrology and sediment supply on channel size and, subsequently, fish habitat quantity as determined in conjunction with the IF Study.

Regressions of channel size are expected to be of greatest potential utility in assessing future geomorphic responses, and representative results for width and depth are presented below.

Of the three potential influences on the relationship between hydraulic geometry and bankfull flow in the three study rivers (Figure 16), gravel yield may be the most influential. Visual observations of vegetative community composition on the river banks in the study area did not suggest that variation in vegetative type substantially influenced channel geometry. Similarly, there was little visual difference in channel bedform morphology between the NFK and SFK and, potentially, the UT. However, the available data indicate that the UT is generally steeper and more confined than the other two study rivers, and slope influences gravel yield (Parker et al., 2007). Slope changes tend to occur over a much longer geological time frame, on the order of thousands of years and longer (Parker et al., 2003, 2007); therefore, this parameter is a reasonably consistent means for classifying streams according to gravel yield potential.

To investigate the potential influence of channel slope, the data were classified into three categories, based on an initial visual assessment of patterns in plots of cross-sectional area against channel forming discharge. The categories were:

- Slope less than 0.1 percent—four sites
- Slope between 0.1 and 0.3 percent—21 sites
- Slope greater than 0.3 percent—26 sites

The regressions do not indicate significant differences between slope classes for either width or depth (Figure 19; alpha = 0.05). The width and depth regression lines for slopes less than 0.001 follow expected patterns relative to the lines for steeper sites, as depicted for decreasing gravel yield in Parker et al. (2007), but the number of data points (four sites) is too small for a significant difference to be detected. Collection and analysis of bankfull data for additional sites representative of low channel slopes could potentially lead to a significant difference in regression equation compared with steeper slopes. However, the total length of such segments are relatively short (Figures 6, 7, and 8) overall, and the regression equation slope appears to be similar for all sites. Hence, the influence of channel slope may not be sufficient to warrant classifying stream hydraulic geometry relations based on channel slope classes. A single, universal regression relationship may be reasonable for predicting future channel changes in the three study area rivers.

7.2.3 CHANNEL GEOMETRY RELATIVE TO ALTERNATIVE HYDROLOGIC METRICS

Because making estimates of bankfull flow magnitude involves considerably greater effort and uncertainty than estimates of bankfull width and depth, a possible alternative approach is to plot channel geometry parameters directly against hydrologic-based statistics representing the range of flows influencing channel form. The four metrics evaluated (1 and 5 percent exceedence flow and the 2- and 10-year flood) encompass a substantial range of bedload transporting flows (Wolman and Miller, 1960). Figure 20 shows the correlations between the nominal bankfull flow estimate and the four hydrologic metrics. Figures 21 and 22 indicate that bankfull channel geometry metrics are also correlated directly with any of the four hydrologic metrics. More work is needed to evaluate the relations more precisely, but the initial results suggest that it should be possible to relate changes in hydrology with changes in channel geometry metrics.

7.3 PARTICLE MOBILITY STUDY

The particle mobility study was conducted to resolve some of the initial uncertainty regarding channel forming flows and incipient motion. Eight radio rocks logged movement at times that were generally consistent with hydrograph timing and magnitude, generally moving on the ascending limb of the hydrograph and at comparable flow rates across events (Figure 23; Table 5). Two of the five events had peak discharges slightly greater than 1,000 cubic feet per second, which corresponds approximately to the 4 percent daily exceedence flow. The first event (September 18 to 20) had the highest peak flow, with the river rising 1.24 feet (835 cubic feet per second) during 19 hours and peaking at 1,090 cubic feet per second. Four of the eight rocks (NK5.19, NK5.22, NK8.22, and NK8.5 in Table 5, ID Numbers 19, 6, 3, and 2, respectively, in Figure 23) logged active codes before the first high flow event and were assumed to have readjusted their position in response to unknown factors other than the critical shear stress. Of the rocks used in the study one rock was rejected outright from the analysis due to apparent transmitter malfunctioning of the device itself. (Figure 23, Table 5).

The results for incipient motion were not definitive. The range of Shields stresses calculated for the three incipient motion conditions (no movement, questionable movement, and consistent movement) overlapped considerably (Figure 24); therefore, there was no clearly defined threshold value. The highest Shields stress at which a stone did not move was calculated to be 0.031, and the highest value at which the cause of incipient motion due to shear was classified as questionable was 0.033. The range of Shields stresses computed for stones that were thought to have moved in response to general shear was between 0.015 and 0.043.

These results generally do not contradict the generally accepted threshold range of 0.031 to 0.035 reported by Wilcock et al. (1996) in a thorough field study and summarized by Buffington and Montgomery (1997) for field and flume studies, or the range of 0.027 to 0.063 reported by McNamara and Borden (2004) based on five radio rocks. Dimensionless shear stress estimates with magnitudes below about 0.03 likely reflect a combination of enhanced exposure to the flow of larger particles in the bed grain size distribution (Andrews, 1983) and inaccuracies in shear stress estimation, rather than a real phenomenon. Hence, a critical Shields stress equal to approximately 0.035, based on the bed surface grain size distribution D_{50} value, appears reasonable for use in future assessments of sediment transport in the study area.

7.4 FINE SEDIMENT LEVELS IN SPAWNING GRAVEL

Sediment sampling conducted in support of this study raised the question of whether samples collected in summer, prior to the spawning season, were representative of conditions that would be experienced by eggs and alevins during the fall and winter. A comparison of gravel composition before and after spawning was conducted to address this uncertainty.

The pre-spawning samples were collected in early August 2008. Spawning activity was underway at all sites, but was not overly extensive. Samples could still be collected in undisturbed spawning substrates in the vicinity of redds. A second set of 24 samples was collected in redds in October 2008 after spawning and fall freshets had occurred and just prior to river freeze-up. Fertilized eggs were encountered in seven samples and sac fry in an eighth sample. The eggs were most likely from sockeye salmon. The sac fry were most likely from chum salmon given their states of development in October and observations of predominant species spawning at the spawning gravel sample sites in August.

The results indicated that, in general, the concentrations of fine sediments in the upper 15 centimeters of redds were not significantly different (alpha = 0.05) from background concentrations in late summer and after spawning and fall rains in all three study rivers (Figure 25). The only site with significant before/after differences was the most downstream site sampled in the UT (SGUT1). However, this result was suspected to reflect a bias in sampling locations, where two-thirds and one-third of the samples collected in August and October, respectively were from large-sized substrates containing relatively less fines compared with smaller-sized substrates. Frazil and anchor ice formation were greater in areas with large-sized substrates and limited access to redds (it was notable that the larger-sized substrates were used extensively by spawning sockeye salmon). This difference in sampling distribution resulted in a significantly larger geometric-mean diameter and smaller amount of fines less than 6.4 millimeters in size in the August samples compared with the October samples at SGUT1 (Figure 26).

Average fines concentrations, geometric mean diameter, and Fredle Index values were not significantly different between sites in each of the three study rivers (Figures 27 and 28). The SFK substrates overall were smaller and contained higher fines on average than the NFK and UT substrates, but the differences were not statistically significant (Figure 27). This is also reflected in lower geometric mean diameter and Fredle Index values (Figure 28).

The results generally indicate that gravel quality in the study area is high both before spawning and after fall high flows prior to winter freeze-up. All four gravel quality measures examined predict high survival to emergence on average in all sites except the most upstream site in the UT (Figures 25 and 26). Predicted survival was generally lowest in the SFK (Figures 27 and 28). Of the sites evaluated, the results suggest that fines concentrations and associated survival metrics would be most sensitive to increased fines loading in the upper spawning reaches of the SFK and UT.

8. SUMMARY

The fluvial geomorphology study to date has evaluated broad scale processes and characteristics of the NFK, SFK, UT, and selected tributaries. Most detailed information has been presented for the three mainstem rivers. Descriptions of large-scale physiographic characteristics include: planform, channel confinement, sinuosity, elevation profile, channel bankfull cross-section dimensions, riverbed grain size,

lithology, ice processes, and the influence of beaver. Site-scale characteristics include: bankfull channel cross-section and discharge, sediment transport and particle mobility, and fine sediment concentrations in spawning habitat.

The results indicate that the three study rivers are typical gravel bed channels with bankfull cross-section dimensions, grain size and planform characteristics representative of the range of slopes occurring in the study area. Where local geologic controls exist, the rivers adjust their morphology as expected, such as straightening when confined and fining when the slope decreases. The channel hydraulic geometry relationships are consistent with other alluvial gravel bed channels and do not appear to vary substantially nor sufficiently such that a single universal hydraulic geometry regression relation appears suited for predicting future channel size changes in response to changes in hydrology. The data also suggest that it should be possible to quantitatively relate changes in hydrology to changes in channel size using a direct correlation between various hydrologic flow parameters and bankfull width and depth. Changes in channel slope are not expected to be detectable over geologically short time frames.

The results of a detailed site study of particle mobility conducted on the NFK indicate that incipient motion conditions in the riverbed are typical of gravel bed streams.

Background fine sediment levels in spawning habitat appear to support high survival to emergence in all three study rivers. Fine sediments appear to infiltrate to essentially background levels in the upper approximately 15 centimeters of salmon redds before winter freeze-up.

A literature review of ice formation processes and beaver influences on channels suggest large-scale reach break points may exist, upstream of which the water column freezes completely and beaver are able to construct mainstem dams, respectively. Downstream, ice cover forms and beaver dams are constructed off-channel. These large-scale features may influence characteristic channel cross-section dimensions, riverbed substrate characteristics, and over-wintering and rearing salmonid habitat quantity and quality.

Tributaries draining the Pebble Deposit area contain varying levels of fine sediments and spawning-size gravel that may influence mainstem river fine sediment concentrations and spawning habitat quantity and quality. The relative importance of each tributary source will reflect transport capacity in both the tributary and mainstem channels. The tributary characteristics are reflected, to some extent in mainstem substrate characteristics in each of the three study rivers. The rates at which both fine sediments and spawning sized gravels are supplied to each mainstem channel are unquantified, however, as are input rates of both size classes from eroding mainstem terraces.

10. GLOSSARY

Aggraded—A progressive buildup or raising of the channel bed and/or floodplain due to sediment deposition in response to upstream-downstream imbalances in sediment transport.

Anchor ice—Ice sheet that forms over and within the streambed surface, typically initiated through formation of frazil ice.

Armor layer—A more stable surface layer of larger particles on the streambed formed through selective removal of finer particles by stream flow.

Avu1sion—A change in channel course that occurs when a stream suddenly breaks through its banks—typically bisecting an over extended meander arc.

Backwater—A hydraulic term referring to the upstream impounding effect of a flow constriction or control.

Bankfull channel depth—The cross-section average flow depth at bankfull discharge.

Bankfull channel width—The wetted width of a stream channel during bankfull discharge.

Bankfull discharge—Flow rate corresponding to the water stage which approximates the elevation of naturally formed, alluvial stream banks and just begins to inundate the floodplain; functionally similar to effective discharge.

Bedform—Morphological formation of riverbed causing flow contraction or expansion locally or at reach scale, e.g., dune or mound (local) or riffle (reach).

Bed load—Sediment moving on or near the stream bed and transported by jumping, rolling, or sliding on the bed layer of a stream. See also suspended load.

Bed roughness—Effect of bed surface irregularity on flow resistance; also see Mannings "n" value.

Bed Slope—The stream-wise inclination of the channel bottom, typically calculated as the drop in bed elevation over a specific distance.

Braided channel—A stream characterized by flow within several channels which successively meet and divide. Irregular channel pattern, with few persistent, clearly defined islands. Flow is shallower than confined/meandering and wandering channels and is distributed more evenly among many channels. Channel tends to move about primarily through avulsion process. Sediment deposits distributed throughout channel net as mid-channel bars. Bedload constitutes a significant fraction of the total sediment transport load. Braiding often occurs when sediment loading is too large to be carried by a single channel.

Channel forming flow—Characteristic, geomorphically effective flow rate representing the range of flows transporting the majority of fluvial sediments and, thus, influencing channel form; analogous to effective discharge.

Confined/meandering channel—Single, sinuous channel at low to bankfull flows with occasional islands and sediment deposits forming point and diagonal bars. Meander pattern sinuosity is generally contained between floodplain terraces and valley side walls. Meander migration in downstream direction is limited.

Confinement—A relative measure of the freedom with which a channel can erode its banks and migrate laterally across the floodplain or valley floor, typically calculated as the ratio of floodplain or valley width to channel bankfull width.

Conveyance—The quantitative ability of a channel to move water downstream.

Critical shear stress—The minimum amount of shear stress exerted by flowing water required to initiate particle motion on the streambed surface.

Degradation—A progressive lowering of the channel bed due to upstream-downstream sediment transport rate imbalances.

Dimensionless—A scaled quantity expressed without needing units of length, mass or time; scale independent.

Drainage area—The total surface area upstream of a point on a stream that drains toward that point. Not to be confused with watershed. The drainage area may include one or more watersheds.

Effective discharge—An index flow rate representing a range of flows transporting the majority of fluvial sediments. Corresponds approximately to the flow rate with a magnitude and duration that transports the greatest sediment volume over a period of time.

Entrenchment—Condition where a stream channel is deeply incised into the floodplain, where relatively large flood flows may be fully contained within the bank tops.

Fining—Process or condition of spatial or temporal reduction in mean grain size of the streambed.

Frazil ice—A slush-like ice that forms in the water column.

Grain size distribution—Statistical, frequency-based representation of range of streambed substrate particle sizes in a non-uniformly sized mixture.

Hydraulic boundary condition—Downstream or upstream bounding cross-section in a hydraulic model such as HEC-RAS.

Hydraulic control—A location in the channel that influences the upstream water surface profile over a range of flows by laterally and/or vertically restricting throughflow; e.g., a riffle crest or channel sidewall constriction.

Hydraulic geometry—The study of the interrelationships exhibited along the course of a river, including the linkage between a characteristic discharge and the mean width, depth and slope of the channel.

Hydraulic radius—The cross-sectional area of a stream divided by the wetted perimeter.

Mannings n—A dimensional coefficient used in fluid mechanics to represent the resistance to flow caused by channel or conduit boundaries. The rougher a boundary, the greater the Mannings n value.

Nominal (discharge/depth/width)—First order, initial estimate of a characteristic quantity.

Normal depth—The depth in prismatic open channels for a given uniform flow rate, calculated using Mannings n.

Orthophoto—An aerial photograph used to identify and quantify elevations of vertical features on a landscape.

Planform—The outline or shape of the channel line in the stream-wise direction, projected on the horizontal plane as viewed from above.

Point bar—The convex side of a meander bend that is formed through sediment deposition.

Ravel—Loose stones mantling a steep hillslope.

Refugia— Locations or habitats that are critical for survival and population maintenance.

Regime—A theory of channel formation that applies to streams that make a part of their boundaries from their transported sediment load and a portion of their transported sediment load from their boundaries. Channels are considered in regime or equilibrium when bank erosion and bank formation are equal and sediment input rate equals output rate.

Stade—A substage of a glacial stage marked by a secondary advance of glaciers.

Stage-discharge rating curve—A continuous curve on a graph defining the relation between flow rate and corresponding water surface elevation at a specific stream channel cross-section location.

Substrate framework—Structural space occupied by larger substrate particles.

Substrate matrix—Interstitial spaces between substrate particle framework, into which fine sediments can fill.

Tailspills— The mound of gravel formed by a spawning salmonid that covers deposited eggs.

Thalweg—Location of the deepest portion across a channel.

Underfit channel—A channel with cross-section dimensions larger than that expected based on assessment of current hydrology and effective discharge; typically a relict expression of a preceding, larger scale geologic event or flow rate.

Uniform flow—Condition of constant flow depth, velocity, and cross-section shape along length of channel.

Valley width—The width of a valley floor, perpendicular to the general stream-wise or valley downslope direction.

Water surface profile—Stream-wise section elevation profile of the water surface.

Manning's Channel Roughness Calibration

MANNING'S CHANNEL ROUGHNESS CALIBRATION

Overview. HEC-RAS uses Manning's roughness coefficient, *n*, to incorporate resistance to flow within its calculations of energy and hydraulic grade lines at each cross-section within a hydraulic model. Resistance to flow occurs as a result of changes in vegetation, substrate, or floodplain surface materials. To ensure that appropriate *n* values are used, HEC-RAS models should be calibrated. Calibration occurs through an iterative process that compares changes in *n* values to discharge measurements or an established stage rating curve (see section 6.2.4 Roughness Calculations). Roughness values (*n*) are fine-tuned until model output matches discharge measurements or discharge rating curve values.

This model was calibrated using rating curves for the Surface Water Hydrology Team's continuous gages that were located within the model boundaries. The rating curves were generated by Knight-Piesold consulting. At the time of model production, only draft copies of the Knight-Piesold rating curves were available so these were used for model calibration. Of five gages within the FG model boundaries, two gages were used to calibrate the final model: FGUT9 corresponding to gage UT100D and FGSK10 corresponding to gage SK100C. UT100E gage was deemed too close to the downstream boundary of the model to be used for accurate calibration. Further, FGUT2 (corresponding to UT100B) and FGUT7 (corresponding to UT100C2), were not used because rating curve equations were not available at the time of the analysis. The below tables provide information used to calibrate the model. Areas highlighted in yellow represent *n* values where model discharge matches the Knight-Piesold draft rating curves.

Notes:

Rating curve, cross-section data, vertical datum, and field notes provided to IFI by HDR. Rating curve calculated by Knight-Piesold. Version used in the calibration of Manning's channel roughness is a DRAFT copy. Gage cross-section incorporated into FGSK10 hydraulic model between IFI surveyed cross-sections 7 and 8. An iterative process was used whereby a roughness was entered into the model for all in-channel roughness values. The range of discharges of interest was run in the model ("Q, model" in table above). Water surface elevations were then exported at the cross-section of interest ("h, model" in table above), modified by the correction factor calculated between the gage vertical datum and the fluvial geomorphology datum (396.97 feet), and then entered into the rating curve to come up with "Q, rating curve". Channel roughness is calibrated when "Q, model" is equal to "Q, rating curve" (highlighted in yellow).

a. Q = discharge (cubic feet per second)
b. h = stage (feet)

Notes:

Rating curve, cross-section data, vertical datum, and field notes provided to IFI by HDR. Rating curve calculated by Knight-Piesold. Version used in the calibration of Manning's channel roughness is a DRAFT copy. Gage cross-section incorporated into FGSK10 hydraulic model between IFI surveyed cross-sections 7 and 8. An iterative process was used whereby a roughness was entered into the model for all in-channel roughness values. The range of discharges of interest was run in the model ("Q, model" in table above). Water surface elevations were then exported at the cross-section of interest ("h, model" in table above), modified by the correction factor calculated between the gage vertical datum and the fluvial geomorphology datum (396.97 feet), and then entered into the rating curve to come up with "Q, rating curve". Channel roughness is calibrated when "Q, model" is equal to "Q, rating curve" (highlighted in yellow).

a. Q = discharge (cubic feet per second)
b. h = stage (feet)

Manning's Floodplain Roughness Reference

MANNING'S FLOODPLAIN ROUGHNESS REFERENCE

Overview. The below 11 locations were used as reference sites to develop Manning's roughness values (*n*) for inclusion in the HEC-RAS model. These locations were chosen as representative of all roughness conditions seen within the project boundaries. Three IFI hydraulic engineers were asked to independently developed a roughness value (utilizing methods described in Arcement and Schneider (1987) and Barnes (1967)). The results of these analyses were then discussed and averaged. The following are each of the 11 reference locations, their reference site ID, finalized roughness values, and a brief site description.

Reference Site	FGNK1
Roughness Value (n)	0.13
Mature willows; 2-3' high grass; low bank	

Reference Site	FGNK6
Roughness Value (n)	0.09
3-4' high grass; clumps of shrubby willows; hummocky ground	

Reference Site	FGNK1
Roughness Value (n)	0.09
Mature spruce; few shrubby willows; low bank	

Reference Site	FGNK5
Roughness Value (n)	0.06
2-3' high grass and horsetails	

Reference Site	FGNK10
Roughness Value (n)	0.09
Trees with medium density grass in understory; low bank	

Reference Site	FGSKt1
Roughness Value (n)	0.06
1-2’ high grass; low bank; slightly hummocky ground.	

Reference Site	FGUT7
Roughness Value (n)	0.07
Low-density mature willows; 2-3' high grass	

Reference Site	FGSK11
Roughness Value (n)	0.07
High banks, very hummocky; 3-4' high grass	

Reference Site	FGNK15
Roughness Value (n)	0.11
Dense shrubby willows; patches of grass 3-4' high; very hummocky ground	

Reference Site	FGNK11
Roughness Value (n)	0.012
Very dense shrubby willows; hummocky ground	

Reference Site	FGNK14
Roughness Value (n)	0.07
Mid-high banks; 3-4' high grassy; hummocky; patches of dense shrubby willow

Site Summaries: Format & Background

Overview. The following attachment includes a site summary for the three fluvial geomorphology (FG) study drainages: North Fork Koktuli River (NK), South Fork Koktuli River (SK), and Upper Talarik Creek (UT). These site summaries are presented in chronological order and provide a detailed account of data collection and analysis efforts.

Each site summary includes the following information:

(1) *Site Characteristics*. These parameters include: stream discharge, latitude, longitude, slope of stream bed, stream width, stream cross-sectional area, D_{50} sediment size (sediment particle size for which 50 percent of the distribution is finer), D_{84}sediment size (sediment particle size for which 84 percent of the distribution is finer), subbasin drainage area, and percent vegetation type (willow, grass, tree).

(2) *Site Overview.* This includes a brief description of survey efforts, why this segment was chosen as a cross-section, and a summary of sediment transport analyses (see *Incipient Motion* for summary of sediment transport analyses and Shield's number).

(3) *HEC-RAS Summary Output Table.* Stream channel characteristics and how they change with increasing flow (discharge) are displayed including:

a. top width – width of water across the top of a cross section
b. channel area – cross-sectional area of flow
c. hydraulic depth - cross-sectional area of flow divided by wetted perimeter (perimeter of channel that water is touching)
d. max depth – maximum depth in a cross-section
e. energy gradient (E.G.) slope -
f. velocity – channel discharge in cubic feet per second (cfs)
g. Froude # - a dimensionless number that describes stream flow conditions, values indicate:
    - Froude # >1 = supercritical flow (fast, rapids)
    - Froude # = 1, critical flow
    - Froude # <1, subcritical (slow)
h. Shear stress – hydraulic force exerted on the channel boundary
i. weighted Manning's *n* – constant for Manning's equation that indicates resistance to flow

These characteristics change with changes in discharge (e.g. depth typically increases with increase in discharge). Results are presented for each reach (e.g. FGNK1) and for river station (the cross-sections surveyed by Inter-Fluve staff). This output was generated using the U.S. Army Corps of Engineers Hydraulic Engineering Center River Analysis System (HEC-RAS). HEC-RAS is a one-dimensional modeling program that uses topographic data and flow information to simulate streamflow.

(4) *HEC-RAS Longitudinal Profile.* This image is a lengthwise view of the entire length of the stream reach, including a streambed profile (streambed elevations from the downstream end are at Main Channel Distance 0, to the upstream end at Main Channel Distance 410). Water surface (WS) elevation profiles are displayed as blue lines and distinguished both by elevation, with the lowest discharge (e.g. WS 1300 cfs) corresponding to the lowest elevation line displayed, and also by variations in geometric shapes present on the lines. Figure 1 highlights some important features of HEC-RAS longitudinal profiles.

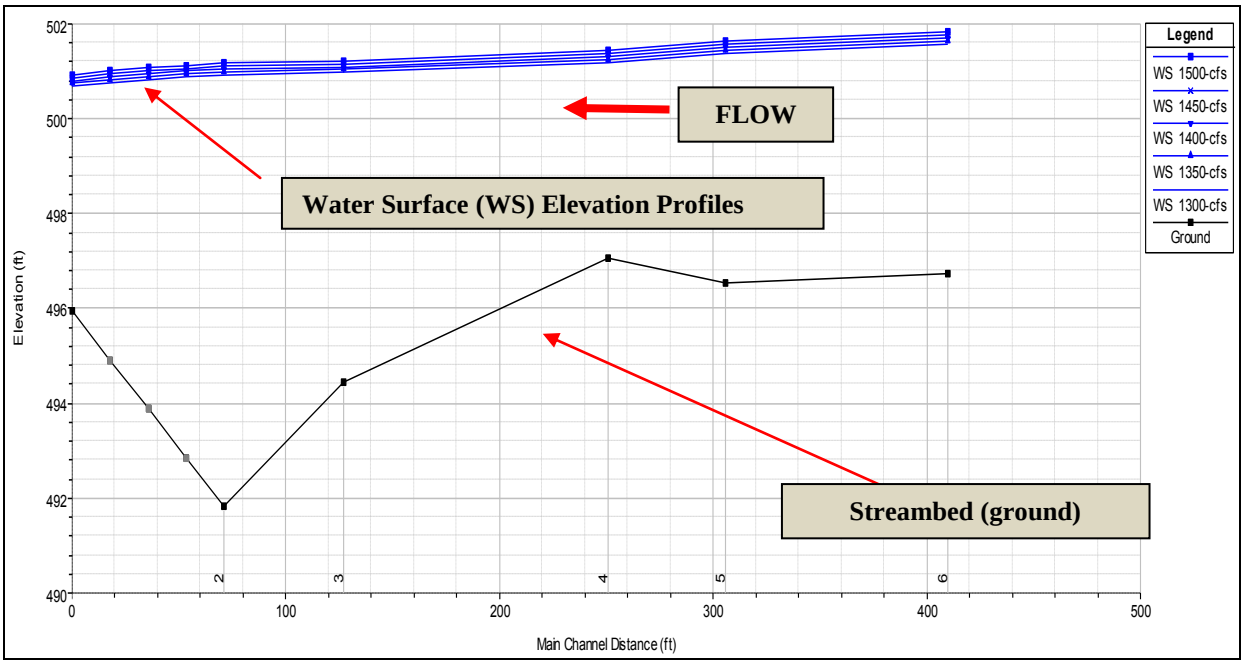

Figure 1 Example HEC-RAS Longitudinal Profile. The streambed ground is represented by a black line and water surface elevation profiles (and how they vary with changing discharges) are represented by the blue lines and referred to in the legend (e.g. WS 1500 cfs)

(5) *HEC-RAS Cross-Section.* These images are channel cross-sections, facing downstream. Station (ft) refers to the total cross-sectional area surveyed from left to right. Figure 2 and Figure 3 demonstrate the relationship between a longitudinal profile and cross-sectional images. Cross-sections are highlighted along the horizontal axis within the longitudinal profile. These numbers correspond to River Station (RS) and within figure labels throughout the document. Again, Water surface (WS) elevation profiles are displayed as blue lines and distinguished both by elevation, with the lowest discharge (e.g. WS 1300 cfs) corresponding to the lowest elevation line displayed, and also by variations in geometric shapes present on the lines. Figure 3 highlights some important features of HEC-RAS cross-sectional images.

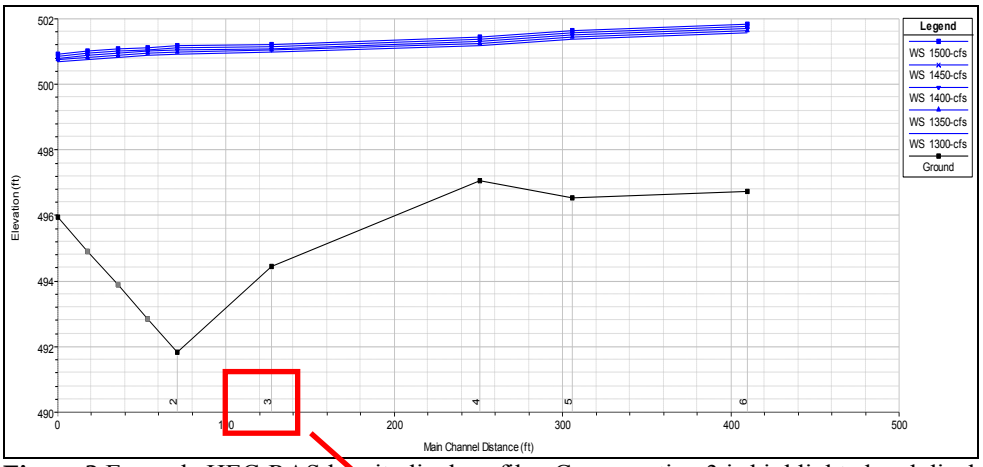

Figure 2 Example HEC-RAS longitudinal profile. Cross-section 3 is highlighted and displayed in figure 3.

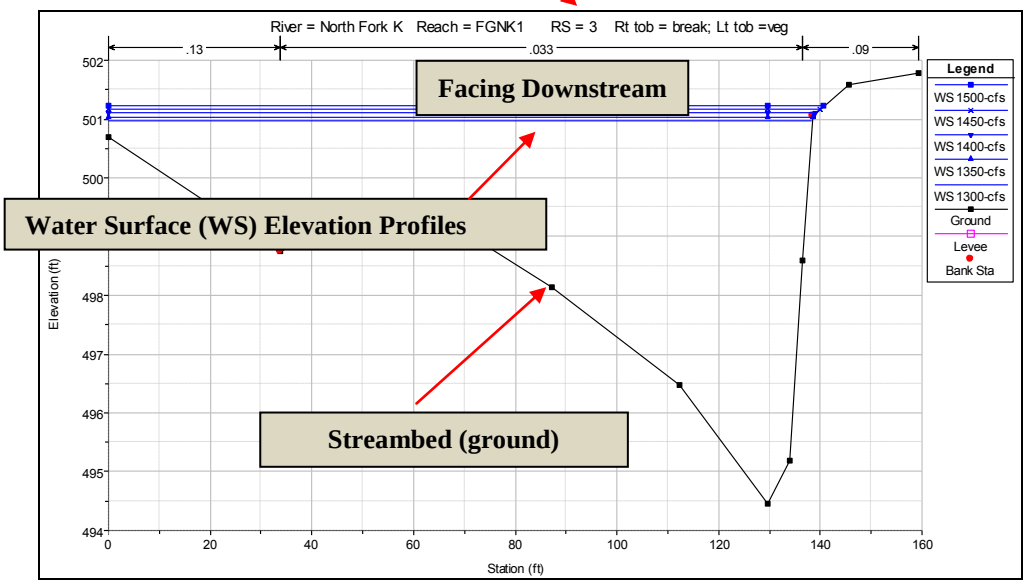

Figure 3 Example HEC-RAS cross-section.

(6) *Incipient Motion Analysis.* The stability of a stream is affected both by the stream's sediment supply and by the pressure exerted by the stream's discharge, or hydraulic force. This hydraulic force, termed *shear stress,* is the force per unit area acting on sediments that make up the channel's streambed and streambank. The channel shear stress affects both the size and quantity of sediments that move through a stream. Shear stress is determined by:

$$\tau_o = \gamma_w R S_f \qquad \text{(Equation T.1)}$$

where:

τ_o = channel bed shear stress (lb/ft^2)
γ_w = unit weight of water, ~62.4 lb/ft^3
R = hydraulic radius (ft)
S_f = friction slope or energy slope

Results from the HEC-RAS model and radio rock study were used to calculate reach-average channel shear stress values for each subreach and for each discharge frequency represented in the model. Hydraulic depth was used for hydraulic radius as an approximation.

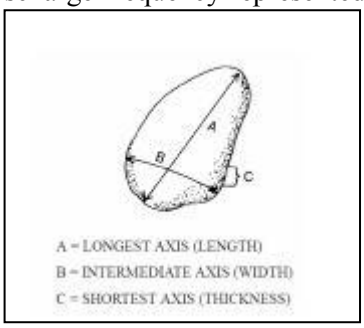

Figure 4 Different axes along a pebble (Wolman 1954)

For this investigation the mobility of the channel bed material was estimated using the Shield's relationship (1936). The Shields equation describes the hydraulic condition at which motion of individual sediment particles may be initiated. This beginning of motion referred to as incipient motion is extensively used in many sediment transport equations and stability relationships. The hydraulic conditions at which incipient motion occurs can be described as the critical shear stress of the bed material. The critical shear stress can be expressed as:

$$\tau_c^* = \frac{\tau_c}{d(\gamma_S - \gamma_W)}, \qquad \text{(Equation T.2)}$$

where:

τ_c = critical shear stress to initiate motion of the bed material (lb/ft^2)
d = diameter of the B axis (see figure 4) of each measured rock before deployment
γ_S = specific weight of radio tagged rocks (weight of rock/volume (lb/ft^3))
γ_W = unit weight of water, ~62.4 lb/ft^3

(7) *Photographic Documentation.* Each site summary provides a detail of the left and right banks, bank composition, and an oblique of the reach.

(8) *Pebble Count Distribution.* This plot and table represent the ranges of pebble (stream substrate) size (from smallest to largest) taken at a given cross-section. One-hundred pebbles are sampled by walking a cross-section and picking up the pebble at your left toe every step for 100 steps (see Fluvial Geomorphology Report 6.1.3) (Wolman 1954).

(9) *Hydrograph.* Where available, USGS flow data (a compilation of measured stream discharges) is presented.

(10) *Site Map.* A reach map displaying the location and River Station (RS) numbering of each HEC-RAS section, points that were surveyed, locations of Wolman pebble count sampling, locations of bulk samples, and surveyed benchmarks.

SITE DESCRIPTION: FGNK1

Site Characteristics.

	Site Name	**FGNK1**	
Discharge (cfs)	**1450 (1300-1500)**	Width (ft)	**76.5 (74.3-78.8)**
Slope	**0.0023**	Cross-sectional Area (ft^2)	**298 (269-319)**
D_{50}	**49**	D_{84}	**85**
Lat/Long Location	**N59.83983 W155.76777**	Drainage Area (mi^2)	**108**
	% Willow	**50**	
	% Grass	**0**	
	% Tree	**50**	

Site Overview. During Inter-Fluve, Inc.'s field efforts in July 2007, field personnel surveyed six cross-sections along 430 feet of channel length. Section 1 serves as the downstream hydraulic control for the model and represents the crest of the pool. A side channel along the right bank of the downstream hydraulic control was surveyed in as well. Due to its angle off the main channel and the size and momentum of the main channel, flow causes this side channel to be ineffective during high flows. The right bank was, therefore, interpolated to complete Section 1. Sections 4 through 6 characterize the riffle that serves as the reference reach through which the pebble count was taken (Section 5).

For a Shields number of 0.017, the D_{84} begins to move at 1,500 cfs through Sections 5 and 6 while for a Shields number of 0.026, the D_{50} has begun to move by 1,350 cfs through the same sections. Both the D_{84} and D_{50} have already begun to move before 1300 cfs on Section 4. These results correlate well with the range of channel forming discharges at FGNK2 and the geometry through the reach.

The reference reach sections (Sections 4 through 6) provide the best representation of the channel dimensions and were used to find average channel width and cross-sectional area over the range of flows.

HEC-RAS OUTPUT SUMMARY TABLE: FGNK1

SITE DESCRIPTION: FGNK2

Site Characteristics.

Site Name		**FGNK2**	
Discharge (cfs)	**1400 (1300-1500)**	Width (ft)	**112 (99.9-123.8)**
Slope	**0.0024**	Cross-sectional Area (ft^2)	**326 (259-391)**
D_{50}	**39**	D_{84}	**73**
Lat/Long Location	**N59.8398 W155.7767**	Drainage Area (mi^2)	**106**
% Willow	**80**		
% Grass	**10**		
% Tree	**10**		

Site Overview. Located just downstream of the USGS stream gage and co-located with surface hydrology site NK100A, FGNK2 serves as a point of reference for the North Fork Koktuli River. Roughly two years of hydrology data (9/04 – 6/06) allowed for an estimate of the frequency and magnitude of discharge events (see attached hydrograph). Additionally, the deployment and monitoring of radio-tagged rocks in the fall of 2007 between cross-sections 4 and 5 provided further calibration of the hydraulic model with an incipient motion analysis.

During Inter-Fluve, Inc.'s field efforts in July 2007, field personnel surveyed six cross-sections along 1200 feet of channel length. Section 1 serves as the downstream hydraulic control for the model and represents the crest of the pool. Sections 4 through 6 characterize the riffle which serves as the reference reach. Recent fish activity within the riffle confined the pebble count and bulk sample to between Sections 4 and 5 along a representative section away from the influence of fish. Since the hydraulics difference between Sections 4 and 5 were great, a section was interpolated within HEC-RAS (Section 4.5*) to account for the location of the pebble count in our incipient motion analysis. The channel is actively eroding along the right bank through the pool (Sections 2-4). A gravel bar has been established at the inside of this bend.

Using Shields numbers of 0.026 for the D_{50} and 0.017 for the D_{84} (see discussion of Radio Tag Study), the D_{84} becomes mobile for a flow not much higher than 1500 cfs on Section 4.5 and between 1400 and 1450 cfs on Section 6. The D_{50} is very mobile throughout the reference reach showing incipient motion prior to 1300 cfs on all sections except Section 5. Geomorphically, the target flow of 1400 cfs shows good agreement with the geometry, notably an inflection point along the left bank of Section 5. This inflection represents the bank and the edge of the willows. Sections 2 and 3 are located in the pool. These inflection points are at the top of the gravel bar where the establishment of young willows effectively acts like a bank, strongly indicating the effectiveness of this range of flows.

SITE DESCRIPTION: FGNK2

The strong agreement between the incipient motion analysis and the site's geomorphic signatures indicate that the channel forming discharge is within the range of 1300-1500 cfs with a target flow of 1400 cfs. This is supported by the hydrology data showing that these flows have occurred three times in the period of record.

The reference reach sections (Sections 4 through 6) provide the best representation of the channel dimensions and were used to find average channel width and cross-sectional area over the range of flows.

HEC-RAS OUTPUT SUMMARY TABLE: FGNK2

HEC-RAS OUTPUT LONGITUDINAL PROFILE: FGNK2

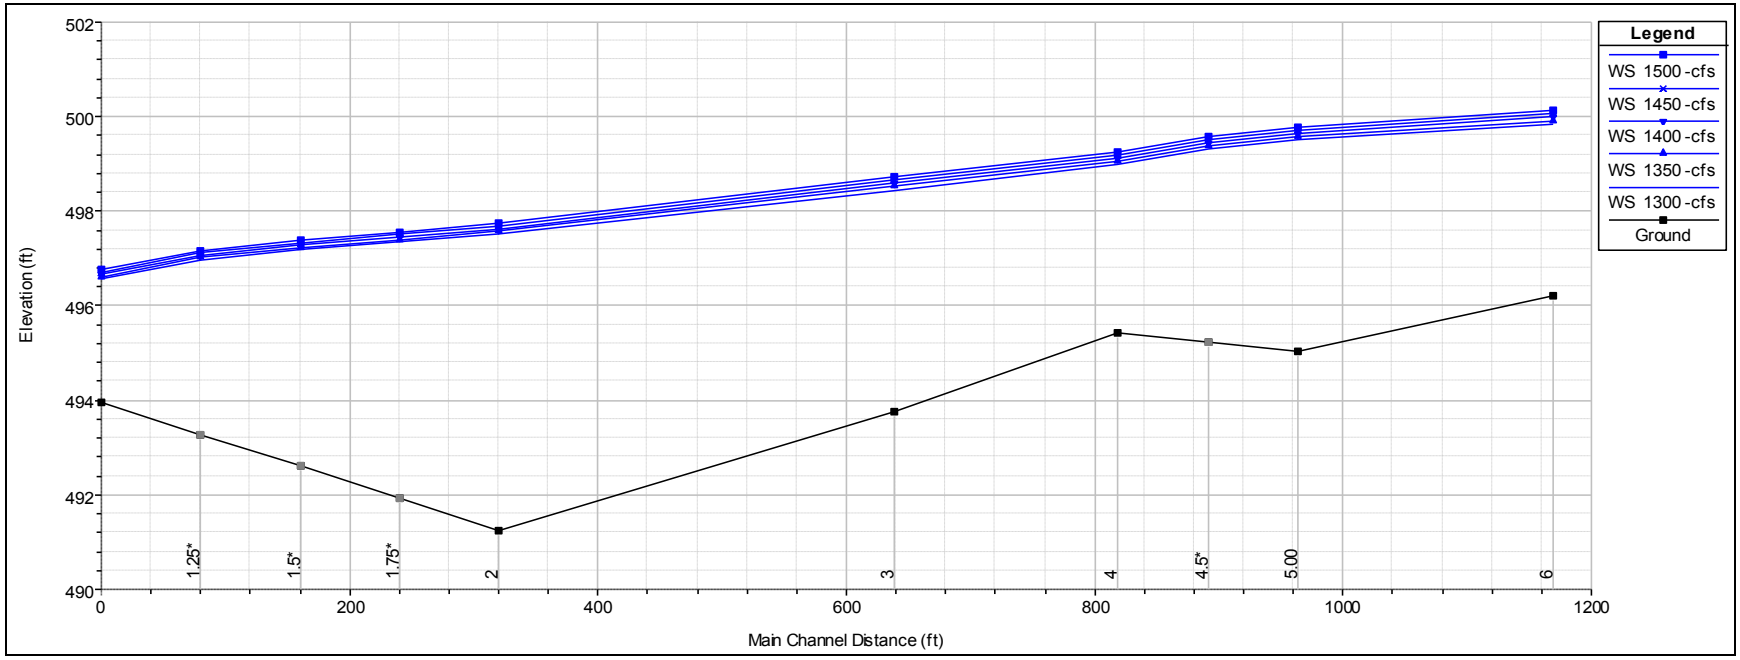

Figure 12 HEC-RAS longitudinal profile output for Reach FGNK2. Numbers 1-6 along the horizontal access correlate to hydraulic cross-sections within the model. Main channel distance (ft) is distance upstream from cross-section 1 (at Main Channel Distance (ft) 0). Blue profile lines represent water surface elevations at selected discharges.

HEC-RAS CROSS-SECTIONS: FGNK2

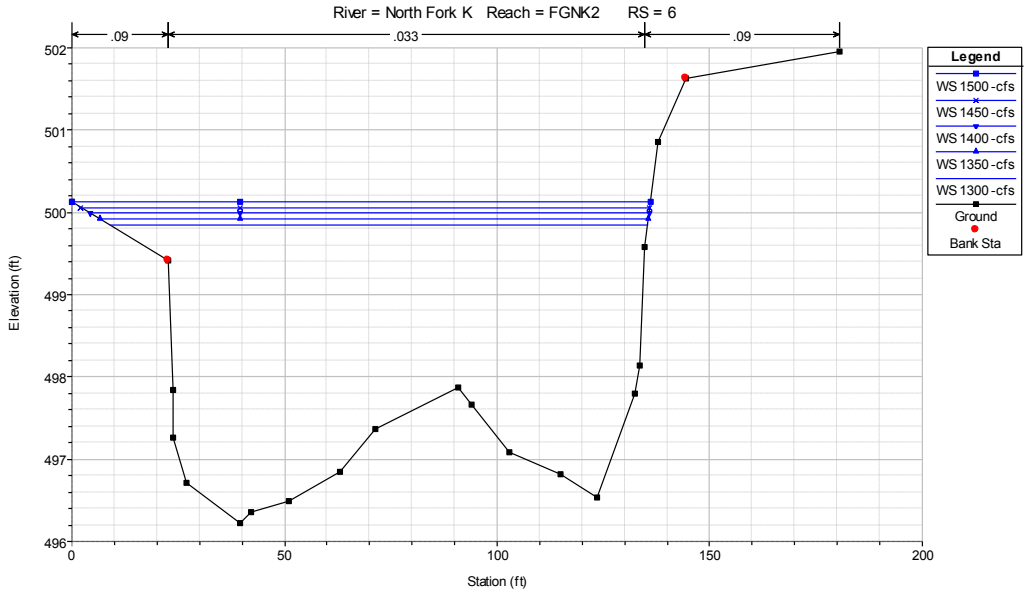

Figure 13 River Station (RS) 6 on River Reach FGNK2. Black line represents the channel ground facing downstream. Station (ft) is distance from the start of the cross-section (station 0). Blue lines represent water surface elevations at selected discharges.

HEC-RAS CROSS-SECTIONS: FGNK2

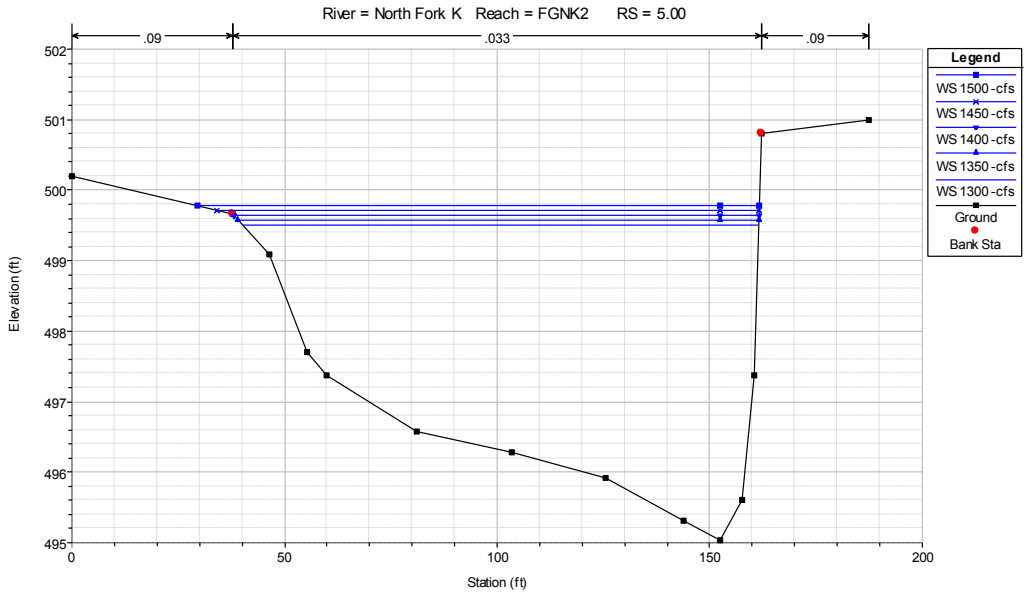

Figure 14 River Station (RS) 5.00 on River Reach FGNK2. Black line represents the channel ground facing downstream. Station (ft) is distance from the start of the cross-section (station 0). Blue lines represent water surface elevations at selected discharges.

HEC-RAS CROSS-SECTIONS: FGNK2

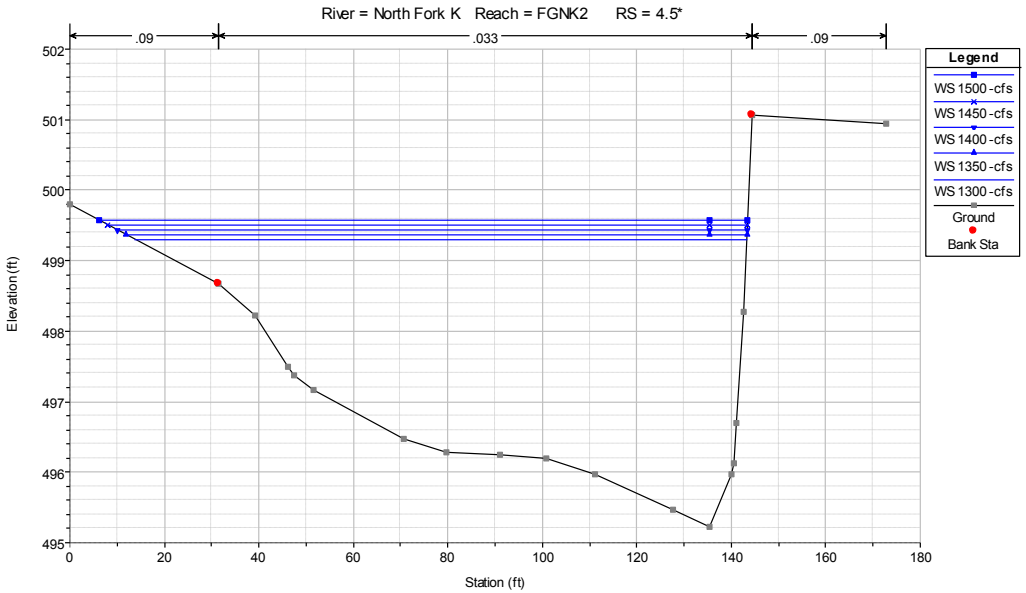

Figure 15 River Station (RS) 4.5 on River Reach FGNK2. Black line represents the channel ground facing downstream. Station (ft) is distance from the start of the cross-section (station 0). Blue lines represent water surface elevations at selected discharges.

HEC-RAS CROSS-SECTIONS: FGNK2

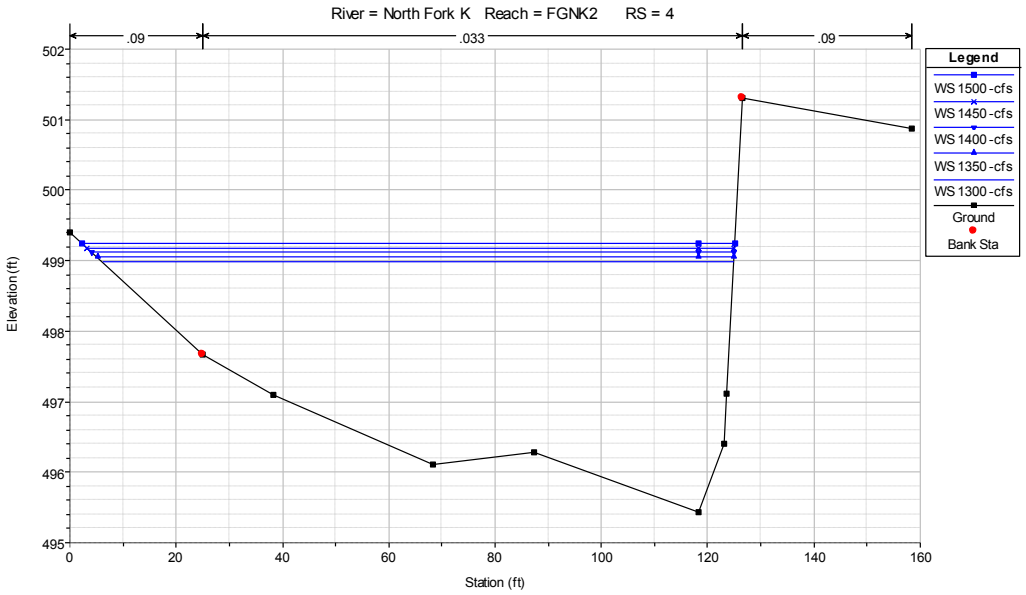

Figure 16 River Station (RS) 4 on River Reach FGNK2. Black line represents the channel ground facing downstream. Station (ft) is distance from the start of the cross-section (station 0). Blue lines represent water surface elevations at selected discharges.

HEC-RAS CROSS-SECTIONS: FGNK2
